

Optimal Labor Market Policy in Developing Countries: A General Equilibrium Analysis

Mitchell VanVuren (Yale)

March 2025

Abstract

Workers in developing countries face substantial constraints to job search. Many policies aim to lower search barriers and expand the wage sector, but the efficiency and optimality of these policies remain unclear. This paper develops a search-and-matching model that incorporates key features of developing economies including a large self-employment sector, savings-constrained households, and capital-constrained firms. Four search externalities — two positive and two negative — emerge, leading to inefficiency. After estimating the model using an experiment that provided search subsidies to job seekers in Ethiopia, I find that the optimal policy is a *tax* that substantially increases the cost of search, rather than a subsidy.

This paper was previously circulated under the title *Job Search in Developing Countries: Crowd-In and Crowd-Out Externalities*. For their helpful comments, I thank David Argente, Kevin Donovan, Niklas Engbom, Joe Kaboski, Hannes Malmberg, Guiseppe Moscarini, Joseph Mullins, David Lagakos, Remy Levin, Kristina Manysheva, Michael Peters, Tommaso Porzio, Valerie Ramey, Pascual Restrepo, Martin Rotemberg, Todd Schoellman, Jedediah Silver, Daniela Vidart, and various seminar participants at UCSD, University of Connecticut, Yale, the NEUDC, Midwest Macro, Y-RISE Annual Conference, and the NBER Summer Institute. I am particularly indebted to Alessandra Peter for her insightful discussion of the paper. Any errors remain my own. 1. Introduction

For policymakers in developing countries, creating jobs is a top economic priority. Recent empirical work, however, has documented that workers face substantial constraints that make it difficult for them to search for work.¹ Simultaneously, the difficulty of finding and hiring the right workers is often understood to be a constraint to firm growth (WDR 2013). As a result, there has been significant interest in policies aimed towards reducing workers' barrier to search — these offer the potential win-win of improving outcomes for workers while also allowing firms to hire the workers needed for growth. Examples of such policies include subsidies to labor search, transport, and the first few months of wages (e.g. Levinsohn et al. 2014, Franklin 2018, De Mel et al. 2019, Abebe et al. 2021a, and many others).

Creating efficient labor market policies in developing countries requires understanding the central tradeoffs underlying search decisions. Frictional search models are the standard tool for answering these questions (see Rogerson, Shimer & Wright 2005, for a review), but lack many relevant features of developing economies. Individuals often spend months or even years alternating between marginal employment and job search before finally finding long-term employment (Donovan, Lu & Schoellman 2023), driven in part by their inability to borrow to fund search (Abebe, Caria, Fafchamps, Falco, Franklin & Quinn 2021a, Abebe, Caria & Ortiz-Ospina 2021b). Thus the household side of any model requires a self-employment outside option and borrowing constraints. Further, it is well-established that firms in developing countries face financial frictions that inhibit growth (Beck, Levine & Loayza 2000, Banerjee & Duflo 2005). To the extent that these frictions also limit hiring, they will play a role in determining optimal policy.

The contribution of this paper is to develop a model of frictional labor markets that takes these central features of developing countries seriously. I characterize the relevant search externalities in this setting and show that novel channels arise from the interaction of search and financial constraints. I then use evidence from a randomized controlled trial in Ethiopia (Abebe et al. 2021a) to estimate the model and quantify these externalities, as well as the tax and subsidy rates that implement the efficient allocation and the resulting welfare gains. I also show that the optimal policy is difficult to determine using partial equilibrium experimental results alone, as these may not represent the impact of the policy when implemented

¹See e.g. Abebe, Caria, Fafchamps, Falco, Franklin & Quinn (2021a), Abebe, Caria & Ortiz-Ospina (2021b)

economy-wide.

In the model, workers have access to a frictionless self-employment option and are savings-constrained, limiting their ability to fund job search. They desire higher-paying wage jobs but must pay a search cost (e.g. commuting) and give up a period of income in order to search. Because they face idiosyncratic job-finding risk, only sufficiently self-insured individuals will choose to search while others will opt for the guaranteed but lower income of self-employment.

A second type of agent — entrepreneurs — operates firms. Entrepreneurs are heterogeneous in productivity and operate a constant returns to scale production technology. Consequently, they desire to be large but are restricted in size by a collateral constraint that prevents them from financing capital beyond some multiple of their wealth. They hire workers by posting vacancies, but vacancies are costly, reducing available collateral and slowing growth. Thus paying these costs today limits firms' ability to expand and offer employment tomorrow.

My interest is in understanding efficiency in this model, and I formalize this idea using a constrained social planner. Motivated by the empirical literature on active labor market policies, I consider a planner that values only worker welfare and cannot adjust firm financial frictions or decisions. For example, in Ethiopia (where I estimate the model), this would be the problem solved by the Ministry of Labor and Skills, which can direct labor market policy but cannot dictate firm or financial policies. The planner therefore chooses the optimal level of search subject to the constraint that firms will respond optimally to their choice and internalizes the impact of these responses on worker welfare.

In standard search models, a worker's decision to search creates congestion costs for other searchers (because it is now harder for them to find a job) but also generates benefits for firms by reducing hiring costs (as firms are more likely to find workers when there are more searchers). These channels are also present here, but their interaction with financially constrained firms adds novel dynamic benefits as well. Successful searchers (those who find jobs) generate profits for firms, which are used to finance asset accumulation and thus firm growth. This benefits future searchers who find jobs at these now-larger firms. Further, I show that this growth is concentrated among high-productivity firms, who are able to leverage this additional capital for growth more effectively. As a result, production tilts towards the most productive firms, reducing misallocation in the economy. Neither of these benefits is taken into account by workers' search decisions, and I refer to

them as the “Firm Size” and “Allocative Efficiency” externalities of search. The optimal policy balances these positive effects against a negative Crowd Out externality.²

The planner’s search decision rule can be implemented in competitive equilibrium by subsidizing or taxing search, but whether search should be subsidized or taxed depends on whether the positive or negative externalities dominate. This is ultimately a quantitative question, and to answer it, I estimate the model using simulated method of moments to match search behavior from fortnightly data collected as part of an experimental evaluation of a labor search subsidy in Ethiopia ([Abebe et al. 2021a](#)). The model is estimated exclusively using data on control individuals (those not receiving a subsidy) while the outcomes of treated individuals receiving the subsidy are reserved for validation checks, which the model passes — while the subsidy is offered, treated individuals are about 5 percent more likely to search for work in both the data and model.

I find that the optimal policy is a tax on search equal to about 50 percent of average self-employment earnings, and the resulting welfare gains are substantial at 1.9 percent of average consumption. Decomposing these gains across the various externalities shows that Crowd Out and Firm Size each have a substantial impact, accounting for 1.5 and -0.8 pp of the gains respectively, while the remaining channels (Allocative Efficiency and the technical externality) collectively contribute only 0.4 pp.³ In essence, the negative Crowd Out effect quantitatively dominates the positive externalities.

What drives the conclusion that Crowd Out dominates and search should be taxed? In traditional search models where the planner maximizes total surplus, efficiency depends largely on the elasticity of the matching function (i.e. [Hosios 1990](#)). This parameter is less important here. Without the ability to control firm decisions, the planner is required to account for firms’ responses to additional search (which are no longer guaranteed to be efficient, given the planner’s lack of control over vacancy postings). If the elasticity of the matching function is small, an additional searcher creates few jobs. However, firms respond to additional search

²The planner also considers a small technical externality related to model design. Valuing only worker welfare, the planner has an incentive to act as a monopolist and restrict labor supply in order to increase wages, an effect common to models that treat workers and entrepreneurs as distinct agents (e.g. [Itskhoki & Moll 2019](#)). This channel is more reflective of modeling assumptions than it is of any interesting economic reality, but, fortunately, it ends up being quantitatively insignificant.

³Due to the nature of the decomposition exercise, the sum of these individual impacts is not necessarily equal to the overall welfare impact of 1.9 percent.

by posting additional vacancies (both in the current period and dynamically due to firm financial constraints), and, if the marginal searcher generates few jobs, the marginal vacancy generates many under a constant returns to scale matching function. The strength of these two channels moves in opposite directions with respect to the match elasticity, diminishing its quantitative importance. This contrasts with a traditional planner who optimally manages the level of search and vacancies separately.⁴

What matters instead is the magnitude of firms' responses to additional search. If small, the additional channels of job creation will be small, and the Crowd Out effect will dominate. This turns out to be the case in the estimated model, driven by the fact that estimated vacancy postings costs are small. The economic environment implied by the data is one in which hiring costs do not represent a particularly large expense for firms, and, as a result, additional searchers have little impact on overall firm hiring or growth — they mostly crowd each other out instead of generating new wage employment through the Firm Size channel. A quantitative experiment confirms this to be the case — substantially increasing the hiring cost targeted in model estimation results in an optimal policy that is a subsidy, rather than a tax, on search.

The final section of this paper pivots from normative to positive analysis and examines the aggregate impact of a search subsidy that reduces the cost of search by two-thirds, the same policy evaluated in the experiment used to estimate the model. The purpose of this section, following in the spirit of the literature on using macroeconomic models to interpret experimental results (e.g. [Brooks, Donovan & Johnson 2020](#), [Lagakos, Mobarak & Waugh 2023](#)), is to highlight the importance of accounting for equilibrium adjustment in determining a policy's impact. The subsidy appears to be a promising policy in partial equilibrium (i.e. without the impact of externalities) and both increases the size of the wage sector (from 30 to 48 percent) and improves welfare (by 2.4 percent). However, these gains are substantially muted once equilibrium adjusts — although the wage sector still grows (to 38 percent), welfare declines by about half of a percent. The subsidy substantially reduces the amount that workers pay to search, but the dominance of Crowd Out leads to a decline in job finding probabilities, extending the average required

⁴Indeed, in classic search models where total surplus efficiency is governed by the Hosios condition (e.g. [Pissarides 2000](#)), imposing this welfare criterion implies that competitive equilibrium is efficient for any value of the elasticity. This knife-edge result does not hold here due to the dynamic forces and financial constraints in my model.

duration of search (from roughly 15 to 17 weeks). As a result, the total expected cost of finding a job (that is, the per-period search cost multiplied by this average duration) falls very little, muting the impact of the policy in general equilibrium relative to partial equilibrium where duration of search does not change.

Overall, the surprising conclusion of this paper is that labor markets in developing countries are characterized by workers who search too much rather than too little, at least for labor markets similar to the one in Ethiopia used to estimate the model where hiring costs represent only a small constraint to firm growth. Consequently, policies aimed at helping and encouraging workers to search, such as search subsidies, run the risk of being counterproductive. While they do manage to increase the size of the wage sector and may even yield promising experimental results, the results are more pessimistic once externalities are taken into account, and these policies carry substantial welfare costs.

Related Literature: This paper is closely related to the macroeconomic development literature studying the impact of entrepreneur-level credit constraints on growth and development such as [Buera, Kaboski & Shin \(2011\)](#), [Moll \(2014\)](#), [Itskhoki & Moll \(2019\)](#), and [Buera, Kaboski & Shin \(2021\)](#). This paper also builds on recent work drawing distinctions between subsistence self-employment and entrepreneurship (such as [Feng & Ren 2021](#)) or otherwise studying unemployment in developing countries (such as [Feng, Lagakos & Rauch 2018](#), [Poschke 2019](#)). Closely related is [Herreño & Ocampo \(2021\)](#) who use a model in which households use self-employment to cope with the risks of wage employment (the same mechanism as this paper) to study the macroeconomic effects of microloans and cash transfers. It is also closely related to other papers that focus on designing optimal labor market policies in developing countries such as [Cirelli, Espino & Sánchez \(2021\)](#) and [Ndiaye, Herkenhoff, Cisse, Dell’Acqua & Mbaye \(2023\)](#), which examine how many of the same features emphasized in this paper impact the design and funding of unemployment insurance.

The model dynamics in which workers flow freely between self/marginal employment and labor search before finding a long-term wage job are very similar to those documented in [Donovan, Lu & Schoellman \(2023\)](#). In a similar vein, [Banerjee et al. \(2021\)](#) find that skilled workers in developing countries exhibit higher unemployment rates relative to unskilled workers and show that this difference leads to differences in occupational choice. [Porzio, Rossi & Santangelo \(2021\)](#) use a model with frictional reallocation of labor from (self-employment dominated) agriculture

to (wage work dominated) non-agriculture to quantify the importance of human capital in explaining the process of structural change.

This paper is also closely related to the microeconomic literature on Active Labor Market Policies, which are intended to help grow the wage sector. [Franklin \(2018\)](#) and [Abebe et al. \(2021a\)](#) both evaluate RCTs of search subsidies. [De Mel et al. \(2019\)](#), [Algan et al. \(2020\)](#), and [Alfonsi et al. \(2020\)](#) all study firm-side interventions (although the last includes an additional worker-side treatment arm) also intended to help workers find jobs. [McKenzie \(2017\)](#) provides an excellent review of this literature.

2. Model

Time is discrete. There is measure one of individuals (workers) and an endogenous number of entrepreneurs. Workers consume, save, and choose between working in self-employment or participating in the frictional labor market for wage jobs. Entrepreneurs operate firms, consume profits, and accumulate capital and labor for future periods.

2.1. Search and Matching Technology

The labor market for wage work exhibits typical search-and-matching frictions. Workers must search for jobs and entrepreneurs must hire by posting vacancies. The cost of searching for a job and the cost of posting a vacancy are denoted by b and c respectively. Each period, the number of worker-firm matches (jobs) is given by a homogeneous of degree 1 matching function $m(S, V)$ where S is the measure of individuals searching for a job and V is the number of vacancies posted by firms. When convenient, $\theta = \frac{V}{S}$ is defined to be labor market tightness so that $p(\theta) \equiv m(\frac{1}{\theta}, 1) = \frac{m(S, V)}{V}$ is the probability that any vacancy is filled and $\theta p(\theta) = \frac{m(S, V)}{S}$ is the probability that any searcher finds a job. Finally, matches between workers and firms are separated with exogenous probability λ at the end of every period, representing the idea that worker or firm needs may exogenously change in a way that causes either to terminate the match.

2.2. Workers

A unit measure of infinitely-lived workers are indexed by their wealth a , their employment status e , and their self-employment productivity y . Their lifetime

utility is given by

$$E_0 \sum_{t=0}^{\infty} \beta^t \frac{c_t^{1-\sigma}}{1-\sigma} \quad (1)$$

Individuals are endowed with one unit of time each period which they supply inelastically and indivisibly to either work or search.⁵

Labor Decisions and Earnings: Any individual can engage in self-employment and operate a linear-in-labor self-employment technology given by $y_t = A_s l_t$. By assumption, self-employment uses only an individual's own labor and does not involve hiring workers from outside the household. For simplicity, I normalize A_s to unity and assume that a workers' "effective labor" l_t follows Markov process M so that self-employment earnings are effectively exogenous, given by the process

$$y_{t+1} \sim M(y_t) \quad (2)$$

Instead of engaging in self-employment, an individual can choose to pay the search cost b and search for a wage job. A searcher earns nothing in the current period and finds a permanent job with probability $\theta p(\theta)$. After finding a job and becoming employed, the individual engages in wage work until they are hit by an exogenous separation shock (in equilibrium, no workers will endogenously quit). Wages are determined via bargaining (discussed later) and depend on the productivity of the entrepreneur with whom the individual is matched, given by z_t .⁶

In total, a worker's earnings are given by

$$\text{Earnings}_t = (1 - e_t)((1 - s_t)y_t - s_t b) + e_t w_t(z_t) \quad (3)$$

where $s_t \in \{0, 1\}$ is a choice variable with $s_t = 1$ corresponding to the decision to search in period t and $e_t \in \{0, 1\}$ is an indicator variable with $e_t = 1$ indicating that the individual is employed in period t .

Budgets: Workers face incomplete markets a la [Aiyagari \(1994\)](#), [Bewley \(1977\)](#), and [Huggett \(1993\)](#) and accumulate assets for self-insurance. Each period, assets

⁵Quantitative experiments with allowing workers to choose any mixture of work and search, rather than being restricted to committing to a single choice for an entire period, suggest that the optimal policy is fairly close to "bang-bang", with individuals largely choosing to allocate their entire time budget to either work or search rather than a mix of the two, for reasonable parameters. Thus the assumption that time is supplied indivisibly is of little quantitative consequence.

⁶Section 2.4 shows that the bargained wage depends only on the productivity of the entrepreneur and not on other entrepreneur or individual state variables.

pay an exogenous rate of return r (i.e. this is a small open economy). Individuals cannot borrow (i.e. $a_t \geq 0$), and their budget constraint is given by

$$a_{t+1} + c_t = (1 + r)a_t + \text{Earnings}_t \quad (4)$$

Search: Search is undirected, and every vacancy has an equal probability of being filled. Conditional on matching with any job, an individual's probability of being matched with job that will pay $w(z)$ is denoted $H(z; X)$ (where X is a vector of aggregate state variables) and is equal to the share of vacancies posted by z -type entrepreneurs. Note here the implicit restriction that w and H depend only on z and not on other worker or entrepreneur state variables. This restriction will be justified in a later section

Separation: Employed workers are separated from their jobs with exogenous probability λ , representing the idea that worker or firm needs may change over time, resulting in the termination of matches. Workers can also lose their jobs if the entrepreneur employing them dies (probability $1 - \Delta$, discussed below) or chooses to downsize its labor force. Under generous parameter conditions (satisfied in the quantified model and assumed throughout the rest of the paper), it can be shown that downsizing never occurs in equilibrium. Thus the probability that an employed worker retains their job at the end of the period is given by $(1 - \tilde{\lambda}) = \Delta(1 - \lambda)$.

Bellman Equation: Taking all of the above, the individual's optimization prob-

lem can be written recursively as

$$\begin{aligned}
V_u(a, y; X) &= \max_{c, a', s \in \{0,1\}} \frac{c^{1-\sigma}}{1-\sigma} + \beta \left((1 - s\theta p(\theta)) E_{y'} [V_u(a', y'; X') | y] + \right. \\
&\quad \left. s\theta p(\theta) (E_z [V_e(a', z; X')]) \right) \\
V_e(a, z; X) &= \max_{c, a'} \frac{c^{1-\sigma}}{1-\sigma} + \beta \left((1 - \tilde{\lambda}) V_e(a', z; X') + \right. \\
&\quad \left. \tilde{\lambda} E_{y'} [V_u(a', y'; X')] \right) \\
s.t. \quad a' + c &= (1 + r)a + (1 - s)y - sb \quad \text{for } V_u \\
a' + c &= (1 + r)a + w(z) \quad \text{for } V_e \\
X' &= G(X) \\
y' &\sim M(y) \\
z &\sim H(z; X)
\end{aligned} \tag{5}$$

where X is a vector of aggregate state variables and G is the perception function for the evolution of the aggregate state. V_u and V_e denote the value function of the individual while unemployed and employed respectively. For simplicity, an individual who moves from employment to unemployment draws their self-employment productivity y from the stationary distribution of M .

2.3. Worker Behavior

Workers weigh the costs of search, the explicit cost b and the opportunity cost of forgone self-employment earning, against the benefit of potentially finding high-paying wage work. This benefit, however, is highly uncertain, particularly if the probability of finding a job is small as it is in many developing countries. It has a fairly small chance of yielding a very large benefit (a successful match) but high probability of yielding no benefit (no match) and leaving the worker substantial worse off than if they opted for the lower but guaranteed income of self-employment.

Because workers are risk-averse, face incomplete markets, and have no way to insure against risk other than self-insurance via asset accumulation, only those

with enough assets to maintain a reasonable level of consumption in the likely situation that they fail to find a job will opt for search. Those without much self-insurance will opt instead for self-employment. For those that search, the search cost quickly depletes their savings and reduces their self-insurance, eventually driving them to self-employment until they can re-accumulate assets.

The result is that workers near the threshold of self-insurance spend a few periods working in self-employment and accumulating assets, then switch to searching for a wage job for a few periods, and return to self-employment once their savings have been depleted. The exact cutoff in savings above which households decide to search depends on their self-employment income y_t which is stochastic, leading to unpredictability in the exact timing of switches.

Figure 1: Worker Self-Employment and Wage Sector Behavior over Time

Note: This figure plots a simulated individual's search, wage work, and self-employment behavior as well as assets over 500 periods. The model used to perform the simulation is based the estimated model described in Section 4 with some features exaggerated to make the underlying behavior clearer.

Figure 1 displays an example of this behavior for a single individual simulated for 500 periods (each period corresponds to a fortnight). The x-axis displays time while the y-axis displays the individual's stock of assets. Green points correspond

to weeks where the individual is engaging in self-employment, red points represent search, and blue points represent wage work. At the start, the individual is near the threshold of self-insurance and alternates between working in self-employment and searching for wage work depending on their particular level of assets and self-employment productivity. Shortly after period 100, their search is successful, and they acquire a high-earning wage job and quickly accumulate assets. They eventually separate from their employer but use their stock of assets to fund extensive search and remain in the wage sector. This behavior continues for quite some time until approximately week 350 when the individual exhausts their assets without finding a job and returns to self-employment punctuated by brief periods of search.

2.4. Entrepreneurs

Entrepreneurs operate wage-sector firms and employ workers. Including entrepreneurs as distinct agents instead of an occupational choice for workers (as in Buera, Kaboski & Shin 2021) reflects the qualitative difference between “subsistence self-employment” and productive entrepreneurship with the potential to grow and employ many workers (e.g. Schoar 2010), in addition to providing a dramatic increase in tractability.

There are N entrepreneurs each of size $\frac{M}{N}$ born every period, and the model considers the limit $N \rightarrow \infty$.⁷ At the end of a period, entrepreneurs die with probability Δ . Entrepreneurs are born with idiosyncratic ability z drawn from some distribution with bounded support $h(z)$ and an initial level of financial wealth \underline{f} (taken to be exogenous). They discount the future at rate β (the same rate as workers) and receive lifetime utility from consumption (labeled d_t for “dividends”) given by

$$\sum_{t=0}^{\infty} (\beta \Delta)^t \frac{d_t^{1-\sigma}}{1-\sigma} \quad (6)$$

Each entrepreneur operates a Cobb-Douglas production technology that depends on their ability, rents capital from the international capital market at an exogenous rental cost $(r + \delta)$, and pays workers wage w_t (determined by bargaining)

⁷The assumption that there are an infinite number of atomic entrepreneurs rather than a measure of non-atomic entrepreneurs is not typical but eliminates many technical difficulties in the discussion of wage bargaining. Other than this, there are no substantive differences between the two assumptions.

so that period profits are given by

$$\pi_t(z, k_t, n_t) = zk_t^\alpha n_t^{1-\alpha} - (r + \delta)k_t - w_t n_t \quad (7)$$

Entrepreneurs face financial frictions and must use their own assets f_t as collateral to finance capital which restricts their size despite constant returns to scale. Their collateral constraint is given by

$$k_t \leq \gamma f_t \quad (8)$$

where $\gamma \geq 1$ is a parameter summarizing the degree of financial market frictions, with $\gamma = 1$ representing the case of full self-financing and $\gamma \rightarrow \infty$ representing no financial frictions.⁸

To hire labor and adjust n_t , entrepreneurs post vacancies v_t . Each vacancy costs c units of output to post and is filled at the end of the period with probability $p(\theta)$. The evolution of n_t is dictated by the equation

$$n_{t+1} = (1 - \lambda)n_t + p(\theta)v_t \quad (9)$$

where λ is the exogenous separation rate. Here, it is worth clarifying that while individuals face idiosyncratic risk in job finding and separation, entrepreneurs do not — an entrepreneur with n_t workers can ensure a labor force of precisely n_{t+1} next period by posting $\frac{n_{t+1} - (1-\lambda)n_t}{p(\theta)}$ vacancies.

Entrepreneurs split their profits between consumption, savings (which are used as collateral tomorrow), and hiring so that their budget constraint is given by

$$d_t + f_{t+1} = \pi_t(z, k_t, n_t) + f_t - cv_t \quad (10)$$

Wage Bargaining: Each period, entrepreneurs and workers bargain over wages. Because capital acts as a fixed factor of production within a period (the collateral constraint always binds in equilibrium), firm output exhibits decreasing returns to scale in labor. To accommodate this, I follow previous literature (Stole & Zwiebel 1996, Smith 1999, Acemoglu & Hawkins 2014) and model production as a cooperative game between workers and entrepreneurs in which each agent is paid their

⁸While this constraint is exogenous, it can be thought of as arising from the unenforceability of contracts or other institutional features that make uncollateralized lending risky and microfounded as such (see e.g. Buera, Kaboski & Shin 2021).

Shapley value.⁹

The entrepreneur enters the game with capital k and workforce n . Any worker that chooses not to cooperate will engage in self-employment for a period and then return to the bargaining table in the next period (i.e. the outside option is a shirking of duties for a period, rather than termination of the match). Defectors draw their self-employment productivity from the stationary distribution of M , but negotiation occurs before these productivity draws are realized so that workers are treated symmetrically and each earns (in expectation) average self employment earnings \bar{y} . If the entrepreneur and x of their n workers choose to cooperate, they operate the entrepreneur's production technology, and produce $zk^\alpha x^{1-\alpha}$.

Each agent is paid their Shapley value arising from this game, so that the wage per worker is given by

$$w = \chi zk^\alpha n^{-\alpha} + (1 - \chi)\bar{y} \quad (11)$$

where χ is a parameter governing the bargaining power of the entrepreneur relative to workers.¹⁰ This wage determination equation is straightforward; workers are simply paid some linear combination of the average product of labor and their outside option \bar{y} , with the weight determined by bargaining power.

Bellman Equation: Combining equations (6) - (10) and the wage bargaining equation (11), the entrepreneur's problem can be written recursively as

$$\begin{aligned} V(z, f, n; X) &= \max_{f', n', k, v, d} \frac{c^{1-\sigma}}{1-\sigma} + \beta \Delta V(z, f', n'; X) \\ \text{s.t. } d + f' &= (1 - \chi)zk^\alpha n^{1-\alpha} - (r + \delta)k - (1 - \chi)\bar{y}n + f - cv \\ n' &= (1 - \lambda)n + p(\theta)v \\ k &\leq \gamma f \\ v &\geq 0 \\ X' &= J(X) \end{aligned} \quad (12)$$

where X is a vector of aggregate state variables and J is the entrepreneur's perceptions function for the evolution of the aggregate state. Notably the composition of

⁹It is worth noting that while I model the production game directly, the microfoundations in [Stole & Zwiebel \(1996\)](#) contain an error and do not actually justify the use of Shapley values in the presence of decreasing returns. [Brügemann, Gautier & Menzio \(2019\)](#) note this error and provide an alternative bargaining protocol that correctly microfound the Shapley values.

¹⁰At a technical level, the game is between an atomistic entrepreneur and a continuum of workers so that the parameter χ is the relative size of the atomistic entrepreneur.

the entrepreneur's work force does not need to be tracked as a state variable due to the fact that bargained wages depend only on z . The full definition of recursive competitive equilibrium is relegated to the appendix.

2.5. Entrepreneur Behavior

While the entrepreneur's problem is complex, it results in fairly simple steady-state behavior (largely due to the fact that an entrepreneur's cost structure is entirely linear) which is summarized in Proposition 1 below.

Proposition 1 *Consider the entrepreneur's problem (12) in steady-state recursive competitive equilibrium, and let $\bar{\theta}$ denote the steady-state value of labor market tightness.*

Then the entrepreneur's optimal policy functions for capital k^ , next period savings f'^* , and next period labor n'^* satisfy*

$$k^* = \gamma f \tag{13}$$

$$f'^* = g(z, \bar{\theta}) f \tag{14}$$

$$\frac{\gamma f'^*}{n'^*} = \eta(z, \bar{\theta}) \tag{15}$$

where g and η depend only on an entrepreneur's productivity z and steady-state tightness $\bar{\theta}$. In particular, they do **not** depend on firm size through either f or n .

Proof: Refer to Appendix B.

In essence, Proposition 1 says that entrepreneurs pick constant capital-labor ratios (η) and growth rates (g) that do not change over the course of the entrepreneur's life. An entrepreneur is born, observes their productivity z and labor market conditions $\bar{\theta}$, chooses a capital-labor ratio and a growth rate, and sticks to those for their entire life. Together, the two functions η and g are sufficient to fully characterize entrepreneur behavior in steady-state.

In addition to lending conceptual clarity, these results are important in keeping the model tractable. Although the bargained wage $w(z)$ could depend in general on all entrepreneur and worker state variables, combining the wage bargaining equation (11) with the unchanging capital-labor ratio (15) which depends only on entrepreneur productivity z yields the result that wages also depend solely on z . Consequently, equilibrium can be computed by solving for a one-dimensional wage function, rather than a four- or five- dimensional one.

To facilitate discussion of efficiency and optimal policy, it will be useful to note

a couple properties of η and g . In particular, we have that

$$\frac{d\hat{\eta}}{d\theta} > 0 \quad (16)$$

$$\frac{d\hat{g}}{d\theta} < 0 \quad (17)$$

The first inequality ($\frac{d\hat{\eta}}{d\theta} > 0$) says that capital-labor ratios are increasing in labor market tightness — a tighter labor market raises hiring costs and increases the price of labor relative to capital and, as a result, entrepreneurs opt to tilt their input mix more towards capital. The second ($\frac{d\hat{g}}{d\theta} < 0$) tells us that growth rates are decreasing in tightness — paying more for hiring diverts income that otherwise would have been saved and used to finance expansion, capturing the idea that poor labor market conditions may serve as an impediment to firm growth.

3. Efficiency and Optimal Policy

As in many models of frictional search, there is a tension between the private benefit of search that accrues to an individual worker and the public/social benefit of search. This tension stems from a disconnect between the number of jobs that workers perceive as being created by their decision to search and the number of jobs that are actually created.

Short-run Job Creation: From a worker's perspective, the expected number of jobs created in the short-run by a period of search is $\theta p(\theta)$ — the probability of finding one job in one period of search. In reality, however, total job creation differs from the worker's perception, and a hypothetical social planner would value search differently. The marginal searcher generates $\frac{\partial m}{\partial S}$ new matches/jobs directly, and this can be reexpressed as $\varepsilon_{m,S}\theta p(\theta)$ where $\varepsilon_{m,S}$ is the elasticity of the matching function with respect to the number of searchers.¹¹ Noting that $\varepsilon_{m,S}$ is typically less than one by assumption, this suggests that workers perceive their direct impact on job creation ($\theta p(\theta)$ new jobs) to be larger than it is in reality ($\varepsilon_{m,S}\theta p(\theta)$ new jobs), a common effect in frictional search models.

There is, however, an additional channel through which searchers create jobs in the short-run. An additional searcher loosens the labor market and lowers hiring costs and, as a result, firms respond in equilibrium by posting additional vacancies

¹¹Although this elasticity is not necessarily constant and, in general, depends on the number of searchers and vacancies, treating it as a constant parameter here facilitates discussion without loss of generality.

(recall equation 16). These vacancies also generate matches. Thus the marginal searcher creates jobs both directly, as above, but also indirectly due to these firm responses. Slightly abusing notation to let $\frac{d \log V}{d \log S}$ represent “the percent change in aggregate equilibrium vacancy postings in response to a one percent increase in the aggregate number of searchers”, we differentiate the total number of jobs created each period $m(S, V(S))$ by S to obtain the total short-run job creation by the marginal searcher

$$\underbrace{\frac{dm(S, V(S))}{S}}_{\text{Short-run Job Creation}} = \theta p(\theta) \left(\underbrace{\varepsilon_{m,S}}_{\text{Direct}} + \underbrace{(1 - \varepsilon_{m,S}) \frac{d \log V}{d \log S}}_{\text{Indirect}} \right) \quad (18)$$

where I have made use of the fact that $\frac{\partial \log m}{\partial \log V} = 1 - \varepsilon_{m,S}$ due to constant returns to scale.

This expression for job creation makes it clear that the aggregate response of vacancies V to an additional searcher plays a central role in governing the extent to which workers overestimate the amount of jobs created by their search. Consider, for example, the case of no collateral constraints, $\gamma \rightarrow \infty$, which corresponds to a typical free-entry-of-firms assumption. In this case, $\frac{d \log V}{d \log S}$ is equal to one as free entry pins down the value of θ . Then total job creation of the marginal searcher is equal to $\theta p(\theta)$, just as workers believe, and there is no misperception at all. Conversely, the difference between workers’ perceptions and truth is maximized when $\frac{d \log V}{d \log S}$ is zero. This result suggests that the magnitude of firms’ responses to searchers plays a key quantitative role in determining optimal policy, and I return to this fact in Section 4.

Long-run Job Creation: In addition to disagreement about how many jobs are created by search in the short-run, a worker and a hypothetical social planner also disagree on long-run job creation. From the worker’s perspective, searching and successfully finding a job today “generates” $(1 - \tilde{\lambda})$ jobs (on average) tomorrow — the probability that the worker is not hit with a separation shock and continues their employment. More generally, finding a job in period t generates $(1 - \tilde{\lambda})^\tau$ jobs in period $t + \tau$.

In reality, however, a new job generated by a searcher today leads to more than $(1 - \tilde{\lambda})^\tau$ jobs τ periods in the future. This fact arises from the presence of entrepreneur collateral constraints — an employed worker today leads to more employment tomorrow not only through the continuation of their own job, but

also because some of the output produced by the worker is captured by the entrepreneur (via bargaining) and can be used to fund firm expansion, including hiring. In particular, combining equations (14) and (15) from Proposition 1 yields a firm-level employment evolution equation of

$$n^{t*} = g(z; \bar{\theta})n \quad (19)$$

which suggests that one additional employee (n) today will lead to g additional employees tomorrow. Adjusting for the firm survival probability (Δ), we see that a new job at a z -type firm in period t generates $(\Delta g(z; \bar{\theta}))^\tau$ jobs in period $t + \tau$.

3.1. The Constrained Planner's Problem

Formalizing the intuition above requires defining a social planner's problem in order to make these externalities/disagreements explicit, but it is not immediately clear what the appropriate problem is. As in much of the search literature, the problem of an all-powerful planner free from any financial constraints or labor market frictions is uninteresting (except perhaps as a benchmark); this planner would simply allocate all labor and capital to the most productive entrepreneur and divide output in a way that equalizes marginal utility across all households and entrepreneurs, which teaches us nothing about search externalities.

Instead, I consider the problem of a government agency or ministry tasked with the goal of improving worker welfare by implementing labor market policy.¹² Importantly, this means that the planner can implement neither firm-side policy (i.e. forcing firms to hire or fire workers) nor financial policies (i.e. adjusting worker or firm financial constraints to allow better risk-sharing or access to credit). This policy-motivated assumption is driven by practical concerns — this is the type of problem that a ministry/department of labor would solve and serves as a natural benchmark against which to judge labor market policies.

Formally, this amounts to a constrained social planner's problem. As in standard search models, the planner cannot overcome search frictions and must respect the search-and-matching technology. Further, the assumption that the planner cannot complete financial markets is encoded in a constraint requiring them to respect workers' and entrepreneurs' individual borrowing/collateral constraints (as in Davila et al. 2012). Finally, I require that the planner's decisions for entrepreneur

¹²Introducing positive weight on entrepreneur welfare can be done, as I show in Appendix C.2, but adds very little additional insight.

vacancy postings, savings, and consumption be consistent with entrepreneur optimality, essentially removing the planner's ability to dictate firm policy. In addition to the practical concerns outlined above, this assumption acts to tie the planner's hands in a way that prevents them from improving outcomes simply by reducing aggregate misallocation. If the planner had the ability to dictate vacancy postings, for example, they could force unproductive entrepreneurs to post no vacancies and allocate employment to only the most productive entrepreneurs. This is an improvement, to be sure, but not one that stems from improving search decisions and thus not part of the underlying intuition we wish to encode in the planner's problem.

Allocations satisfying these constraints make up the set of feasible allocations for the planner, leading to the following definition:

Definition: A path of household policy functions $\{c_t(a, y, z), a'_t(a, y, z), s_t(a, y, z)\}_{t=0}^\infty$, entrepreneur policy functions $\{g_t(z), \eta_t(z)\}_{t=0}^\infty$, distributions of households across savings and matched-employer productivities $\{m_t(a, z)\}_{t=1}^\infty$, and labor market tightnesses $\{\theta_t\}_{t=0}^\infty$ is **feasible** given an initial distribution $m_0(a, z)$ and market tightness θ_{-1} if

1. It respects the household budget constraint for all a, y, z

$$\begin{aligned} a'_t + c_t &= Ra + w_t(z_t, \theta_t) & \forall a, y, t \text{ when } z \geq 0 \\ a'_t + c_t &= Ra + (1 - s_t)y + s_tb & \forall a, y, t \text{ when } z = 0 \\ a'_t &\geq 0 \end{aligned} \quad (20)$$

2. It respects the labor market matching technology

$$\begin{aligned} \frac{v(m_t, \eta_t, \eta_{t+1}, g_t)}{\theta_t} &= \int \int s_t(a, 0) m_t(a, 0) j(y) dy da \\ m_{t+1}(a', z) &= (1 - \tilde{\lambda}) m_t(a, z) + H(z, m_t, \eta_t, \eta_{t+1}, g_t) p(\theta_t) v(m_t, \eta_t, \eta_{t+1}, g_t) \end{aligned} \quad (21)$$

where v is the total number of posted vacancies as a function of entrepreneur policy functions, and H is the probability that an individual who finds a job is matched with a firm of productivity level z .¹³

3. The entrepreneur policy functions $\{g_t(z), \eta_t(z)\}_{t=0}^\infty$ solve the entrepreneurs'

¹³Both v and H are formally defined in Appendix C.

problem (Appendix equation 31), conditional on θ_{-1} and $\{\theta_t\}_{t=0}^{\infty}$.

The task of the social planner is to maximize average worker welfare subject to these feasibility conditions. Formalizing the statement of this problem is straightforward but cumbersome and is relegated to Appendix C.

There are two details worth noting. The first is that this definition of the planner's problem implicitly imposes the assumption that there is no autocorrelation in individuals' self-employment productivity y (i.e. the distributions m_t are only defined over (a, z)). This simplification substantially reduces notation, improves readability, and does not change any of the underlying results or economics; I maintain it throughout the rest of the paper. The second is that the planner's problem features full commitment (they choose the entire sequence $\{\theta_t\}_{t=0}^{\infty}$ simultaneously) abstracting from any potential complications of dynamic games between the planner and model agents.

3.2. Privately- vs Socially- Optimal Search Decision Rules

With the planner's problem specified, Proposition 2 formalizes the externalities that were discussed above by characterizing both the privately optimal search decision rule (Individual) and the planner's socially optimal search decision rule (Planner). Differences between the two represent search externalities that are not internalized by workers in competitive equilibrium. For clarity, I make the simplifying assumption that $\sigma \rightarrow 0$ (i.e. linear utility). This assumption is not necessary, and Appendix C provides the statement of the proposition valid for any (time-separable) utility function.¹⁴

Proposition 2 *Under the assumption that $\sigma \rightarrow 0$, the optimal steady-state search policies $s(y)$ of an individual and the constrained social planner depend only on an individual's self-employment productivity and are to search if and only if self-employment productivity y falls below the thresholds s_c and s_p (respectively) which are characterized by the following*

¹⁴The general statement is not substantively different from the statement in Proposition 2 in the sense that the planner's optimal search decision rule differs from the individual's in the same ways. However, the assumption of linear utility substantially improves the readability of equations (22)-(24).

equations:

$$\text{Individual: } s_c + b = \bar{\theta}p(\bar{\theta}) \int_z \frac{\beta E(z, s_c)}{1 - \beta(1 - \bar{\lambda})} \bar{H}(z) dz \quad (22)$$

$$\begin{aligned} \text{Planner: } s_p + b = & \bar{\theta}p(\bar{\theta}) \int_z \frac{\beta E(z, s_p)}{1 - \beta \underbrace{\Delta g(z, \bar{\theta})}_{\text{Firm Size}}} \bar{H}(z) - \underbrace{\frac{(1 - \varepsilon_{m,S})}{1 + \int \frac{\partial \log v^*}{\partial \log S} dz} \bar{\lambda}(z)}_{\text{Crowd Out}} \bar{H}(z) dz + \\ & + \frac{1}{1 + \int \frac{\partial \log v^*}{\partial \log S} dz} \left(\underbrace{\bar{S} \bar{\theta} p(\bar{\theta}) \int_z \bar{\lambda}(z) \frac{\partial H}{\partial g} \frac{\partial g}{\partial S} dz}_{\text{Allocative Efficiency}} + \underbrace{\int_z \frac{\partial w}{\partial \eta} \frac{\partial \eta}{\partial S} \bar{m}(z) dz}_{\text{Monopolist}} + \text{Anticipation Term} \right) \end{aligned} \quad (23)$$

$$E(z, s) = w(z) - \left(\int_{y>s} y j(y) dy + J(s)(s - b) \right) \quad (24)$$

where $E(z, s)$ represents the excess value (over self-employment) generated by a job at a z -type firm, j and J are the PDF and CDF of the distribution of y respectively, and $\lambda(z)$ is the planner's Lagrange multiplier denoting the marginal value of an additional worker being matched with a productivity z entrepreneur. The anticipation term is described further in the appendix.

The privately optimal search rule is fairly straightforward. Workers weigh the opportunity-cost-inclusive cost of search ($y + b$) against its expected benefit. This expected benefit is given by the probability of getting a job next period $\bar{\theta}p(\bar{\theta})$ multiplied by per-period excess earnings while employed E and then discounted according to the expected job duration. The level of income at which workers are indifferent between searching or not, s_c , occurs when these two values are equal. Workers below this level will search, while workers above this level will engage in self-employment.

Search Externalities: Relative to the privately-optimal rule, the planner's socially-optimal rule differs in four ways that are highlighted and labeled in equation (23), and I discuss each in turn.

First, the "Firm Size" term captures the disagreement between workers and the planner over long-run job creation discussed via equation (19) above. Although workers only internalize the fact that employment today increases their own em-

ployment prospects in the future (by $(1 - \tilde{\lambda})^\tau$ for period $t + \tau$), the planner recognizes that entrepreneurs capture some portion of the income generated by employment today and use this to fund future growth and hiring. The planner values these additional jobs, which amounts to increasing the discount rate used for excess earnings by $\Delta g(z, \bar{\theta}) - (1 - \tilde{\lambda})$, the amount of future employment generated by a worker each period in excess of their own continuation probability.

The “Crowd Out” term captures the disagreement over short-run job creation discussed and summarized in equation (18). Although the worker believes that a period of search creates $\bar{\theta}p(\bar{\theta})$ jobs, the planner adjusts this number downwards according to equation (18).¹⁵ Because the marginal searcher creates fewer than $\bar{\theta}p(\bar{\theta})$ jobs, they lower the overall job finding probability. Thus, an alternative and equally valid interpretation of this term is that it arises from the planner internalizing the overall decline in the job finding probability induced by the marginal searcher. This can be seen directly by noting that $(1 - \varepsilon_{m,S})$ is a function of $\frac{\partial \bar{\theta}p(\bar{\theta})}{\partial S}$, the change in the overall job finding probability due to the marginal searcher.

Interestingly, a third term, “Allocative Efficiency”, related to long-run job creation also appears. While the Firm Size effect accounts for the fact that a portion of the output generated by a job is used to finance hiring in the next period and increases the *level* of employment, it turns out that there is also a *compositional* effect. An additional searcher puts downward pressure on labor market tightness and lowers hiring costs, increasing firm growth rates. However, because more productive firms wish to grow faster and thus are more constrained by hiring costs, this leads to a larger increase in growth and employment among high-productivity firms compared to low-productivity firms, increasing productive firms’ share of resources and improving allocative efficiency. From the planner’s perspective, this results in higher worker welfare by increasing the probability that workers match with highly productive firms that pay higher wages ($\frac{\partial H}{\partial g}$).

The final term, “Monopolist”, is a technical externality rather than an economic one. Due to the assumption that the planner values only worker welfare, the plan-

¹⁵The exact equivalence is clear when noting that the aggregate elasticity in equation (18), $\frac{d \log V}{d \log S}$, is related to the individual elasticity in equation (23), $\frac{\partial \log v^*}{\partial \log S}$, via $\frac{d \log V}{d \log S} = \frac{\frac{\partial \log v^*}{\partial \log S}}{1 + \frac{\partial \log v^*}{\partial \log S}}$. This expression can be obtained by differentiating the equilibrium condition $V = \int v^*(z, S, V) dz$ with respect to S and recognizing that constant returns to scale of the matching function imply that $\frac{\partial \log v^*}{\partial \log V} = -\frac{\partial \log v^*}{\partial \log S}$.

ner has an additional incentive to act as a monopolist on behalf of workers.¹⁶ Here, it takes the form of limiting search in order to push up the capital-labor ratio and, consequently, wages ($\frac{\partial w}{\partial \eta} \frac{\partial \eta}{\partial S}$). Fortunately, this technical externality ends up being quantitatively small in the estimated model and contributing little to the optimal policy.

Before moving on, it is worth briefly discussing how these externalities, the Crowd Out effect in particular, compare to the externalities in textbook search models. Crowd Out is conceptually very similar to a traditional congestion externality — one worker’s search lowers others’ chances of finding work — but the size of Crowd Out depends on both the match elasticity $\varepsilon_{m,S}$ and firms’ response to additional search $\int \frac{\partial \log v^*}{\partial \log S} dz$ while traditional congestion depends only on the former (see e.g. equation 14 in Hosios 1990). At first glance, this difference is puzzling. Firms also post vacancies in response to additional search in standard models, so why does such a term appear here and not there?

The key difference lies in the policy-motivated assumption that the planner cares only about worker welfare and is constrained in a way that prevents them from controlling the decisions of firms. In traditional search models, where such a constraint does not exist, the planner can dictate search and vacancy posting decisions separately (or, in the decentralized case, set tax rates to determine these separately). This planner does not need to consider vacancies when determining the optimal level of search because they possess an additional tool to ensure that the marginal vacancy is efficient. In contrast, the constrained planner here does not possess this tool and must consider search and vacancies jointly. Appendix Section C.3 develops this logic further and shows how modifying the constraints faced by the planner can recover the traditional Hosios condition.

3.3. Implementing the Planner’s Allocation

The problem of selecting the welfare maximizing path subject to feasibility conditions is similar to other Ramsey-type problems often found in the literature dealing with welfare and efficiency in heterogeneous agent models (e.g. Davila et al. 2012, Itskhoki & Moll 2019, Dávila & Schaab 2023). Like all Ramsey problems, the planner’s allocation can be decentralized and implemented in competitive equilibrium using a sufficiently rich set of tax and subsidy instruments.

¹⁶This type of externality is common in models that treat workers and entrepreneurs as distinct agents with distinct utility functions (see e.g. Itskhoki & Moll 2019).

Implementing the planner’s allocation in this way, however, turns out not to be feasible in practice. Proposition 2 seems to suggest straightforward implementation — a subsidy or tax that aligns the competitive search cutoff s_c with the planner’s search cutoff s_p should be sufficient. While this does succeed in aligning workers’ search decisions with those of the planner, the subsidy also alters workers’ budget constraints and, as a consequence, the resulting allocation violates the planner’s constraint in condition (20). By definition, such an allocation cannot solve the planner’s problem. Instead, a complex set of state-contingent lump-sum transfers, well beyond the capabilities of any developing country government, is needed to restore feasibility.

To address this, the quantitative analysis below focuses instead on computing optimal subsidy/tax rates on search and self-employment, absent any lump-sum transfers. In order to minimize the impact of eliminating such transfers, the rates are chosen to achieve budget balance (in addition to maximizing welfare) — if the optimal level of search is higher than competitive equilibrium, this is implemented by subsidizing search and taxing self-employment (i.e. the non-search option) in such a way that results in zero net revenue, thus minimizing the impact of the policy on budgets. Fortunately, this change (which is more technical than economic) is of little consequence, and, as I show in Section 5, this restriction changes the results by a negligible amount.

4. Model Estimation

Neither the positive (Firm Size, Allocative Efficiency) nor the negative (Crowd Out) externalities of the previous section can be shown to dominate in general. Consequently, determining the optimal policy — whether search should be subsidized or taxed — is a quantitative question that requires bringing the model to data. This, in turn, requires narrowing our focus to a particular labor market, as many model parameters are likely to vary from country to country and even from city to city. To this end, I opt to estimate the model to match the labor market of Addis Ababa, Ethiopia, largely because a useful experiment for model estimation happened to be conducted there.

I divide model parameters into two categories. The first are parameters that can be computed directly from data (such as collateral requirement γ) or set to standard values (such as the discount rate β). The second are parameters that are more difficult to measure directly (such as the search cost b). These parameters

are estimated using the simulated method of moments (SMM) to match data moments from the aforementioned experiment, as well as some aggregate moments. Before going into the details of the SMM estimation, it is worth briefly discussing a handful of the key parameters that are directly estimated and whose values are important.¹⁷

4.1. Key Directly Estimated Parameters

Importantly, the rate of return on individuals' savings R is taken to be less than unity with an annual value of 0.9 (chosen to roughly match the Ethiopian inflation rate, suggesting that individuals' savings a are best thought of as cash). Because the model is estimated at a fortnightly frequency, this corresponds to a value of $0.9^{\frac{1}{26}}$. The assumption that the return to savings is less than one, and thus that saving is costly, is typical in models of developing countries (see e.g. [Donovan 2021](#), [Fujimoto](#), [Lagakos & VanVuren 2023](#)). Here, this assumption is important as the difficulty of maintaining a cushion of savings is an oft-cited justification for search subsidies.

For similar reasons, the income process of the self-employed is also important. This is measured directly using fortnightly data on workers and job seekers collected by [Abebe et al. \(2021a\)](#) as part of an experiment in Addis Ababa (details below). In the context of Addis, the majority of the variation in earnings (among those without a permanent job) comes from whether an individual is currently working a temporary, gig-style job or not. Consequently, self-employment productivity is modeled as a binary Markov process (with the high state corresponding to "working" and the low state to "not working") whose transition matrix can be estimated directly (the probability of remaining in one's current state is roughly 89 percent for both high and low states). The ratio of earnings between the high and low state can also be measured directly and is set to 2.63. Thus, the model closely matches observed volatility in self-employment earnings.

The matching function is chosen to be a simple urn-ball matching function so $p(\theta) = \frac{1-e^{-\zeta\theta}}{\theta}$, with an efficiency parameter of ζ that can be adjusted to target any elasticity $\varepsilon_{m,S} = -\frac{d \log p}{d \log \theta}$ in the model steady-state.¹⁸ Absent detailed estimates

¹⁷ Although not all parameters are discussed here, Appendix D and, in particular, Appendix Table D.1 provide an exhaustive list of these parameters, their values, and some further discussion.

¹⁸ The choice of functional form is unimportant beyond the fact that it includes a free parameter that can be used to target the desired elasticity for p . A functional form exhibiting a constant elasticity, such as Cobb-Douglas, would be ideal, but the use of discrete time limits sensible choices for

of this elasticity in the context of Addis Ababa and lacking the necessary data to estimate it, I choose ζ to generate an elasticity $\varepsilon_{m,S}$ of 0.3. This is a fairly typical value and is roughly in line with the estimates of [Hall & Schulhofer-Wohl \(2018\)](#) for the United States (quantitative experiments in Section 5 below show that this choice ends up having little consequence for optimal policy).

Finally, many of the entrepreneurs' parameters can be estimated using data from the World Bank. MIX Market data contains financial information on microcredit providers in Ethiopia and suggests a rough average yield of 25 percent which, combined with an 8 percent depreciation rate, suggests a user cost of capital equal to 33 percent annually.¹⁹ The average collateral requirement in Addis Ababa (computed using the World Bank Enterprise Survey for Ethiopia in 2015) is 350 percent — a firm that owned 350,000 Birr of capital could finance a 100,000 Birr loan — suggesting a value of 1.29 ($1 + \frac{1}{3.5}$) for the collateral parameter γ . Finally, fitting a geometric distribution to the firm age distribution via maximum likelihood yields an annual entrepreneur death probability ($1 - \Delta$) of 0.08.

4.2. Parameters Estimated using the Simulated Method of Moments

Table 1: Parameter Estimates from Simulated Method of Moments

Parameter	Estimate	Corresponding Moment
σ	3.6	% wage work
λ	0.05	Unemployment rate
χ	0.50	Wage sector premium
b	0.06	% of expenditure on search
Mf	.002	Control wage employment after 16 weeks
c	0.48	Cost to hire as % of wage
\bar{z}	0.39	Avg. growth rate

Note: This table displays the parameters estimated using simulated method of moments, their estimates, and the moment that corresponds most closely to each parameter. See discussion for details and intuition on these correspondences.

There are seven parameters estimated using the simulated method of moments to match seven data moments. Table 1 lists these parameters and their estimated

¹⁹ to those that lead both $p(\theta)$ and $\theta p(\theta)$ to be bounded between zero and one.

¹⁹Loan loss rates in Ethiopia are negligible for the purposes of this calculation.

Table 2: Moments Targeted using the Simulated Method of Moments

Moment	Source	Data	Model
% wage work	LSMS	30%	29%
Unemployment rate	LSMS	10%	13%
Wage sector premium	LSMS	39%	39%
% of expenditure on search	Abebe et al. (2021a)	15%	16%
Control wage emp. after 16 weeks	Abebe et al. (2021a)	12%	11%
Cost to hire as % of wage	Abebe et al. (2017)	120%	120%
Avg. growth rate	World Bank ES	4.4%	4.4%

Note: This table displays the moments targeted in the simulated method of moments estimation, their source, and their values in both the data and model. See the discussion for details.

values while Table 2 lists the targeted moments and their values in both the data and the model. The parameters fall into two rough categories — those corresponding closely to worker-level moments (above the dividing line in Tables 1 and 2) and those corresponding closely to firm-level moments (below the line).

Worker moments: The data for the worker-level moments come from two sources. The proportion of individuals engaged in wage work and the aggregate unemployment rate are measured using the 2018-2019 wave of the Ethiopia Living Standard and Measurement Survey (LSMS), limited to individuals in Addis Ababa.²⁰ The wage sector premium is estimated on the same data by including a dummy variable indicating whether an individual is employed in a permanent wage job (vs self-employment or temporary work) in an otherwise standard Mincer regression of (log) earnings on age, as well as some controls (rural/urban, region, and sector fixed effects).²¹

²⁰While the other data sources used in estimation are from 2014-2015, the 2018 wave of the Ethiopia LSMS was the first wave capable of providing representative estimates for Addis Ababa (previous waves were not representative at a sub-national level). For this reason, I opt to use the data from 2018 rather than the 2015 wave, which would otherwise be more temporally consistent with the other datasets.

²¹The Ethiopian Productive Safety Net Programme (PSNP), a relatively new (circa 2018) “workfare” program administered by the Government of Ethiopia, presents a potential complication. The program provides temporary employment and was present in some regions of Addis Ababa during the 2018 LSMS survey. It is unclear whether earnings from the PSNP should be included in estimation. Fortunately, dropping individuals employed by the PSNP from the analysis changes the estimated wage premium by less than one percentage point, rendering the issue quantitatively

The two remaining household moments come from the aforementioned data on job seekers from [Abebe et al. \(2021a\)](#). The first is average expenditure on job search (for weeks in which an individual searches) as a percentage of total expenditure. This is calculated directly via survey responses (i.e. individuals are asked directly how much they spent on search and in total). The second, labeled “control wage emp. after 16 weeks”, reflects the proportion of individuals in the experimental control group with permanent employment 16 weeks after baseline. Although I discuss the experiment in more detail in the next subsection, it is important to note here that only data from the experimental control group is used in model estimation, while data from the treatment group is reserved for model validation.

Together, these five moments pin down the five parameters above the dividing line in Table 1. The risk aversion parameter σ and the job separation rate λ are disciplined (mostly) by the size of the wage sector and the unemployment rate. While the link between the separation rate and the unemployment rate is clear, the link between risk aversion and the size of the wage sector arises from the fact that, for the worker, search is the higher-risk, higher-return option (relative to self-employment). Thus individuals’ risk tolerance ends up being a primary determinant of the level of search and, consequently, the size of the wage sector.

The earnings premium in the wage sector naturally pins down the bargaining power parameter, as a higher value (more bargaining power for workers) shifts the bargained wage towards the average product of labor and away from the outside option. The percent of total expenditure that goes towards search costs almost mechanically pins down the goods cost of search. The final moment, the employment rate of control group job seekers after 16 weeks, conceptually pins down the (weekly) job-finding rate. The parameter most directly linked to this equilibrium object is the initial size of a newborn entrepreneur (given by $M\bar{f}$, which are not separately identified) which determines the “size” of entrepreneurs relative to workers — if entrepreneurs are larger, they will post more vacancies, leading to higher job-finding rates.

Firm moments: The remaining parameters — the vacancy posting cost c and the distribution of firm productivity — are estimated to match firm-level moments. [Abebe et al. \(2017\)](#) survey firms in Addis about hiring practices and find that the average cost to a firm of making one additional hire is equal to 120 percent of the average wage. This moment directly pins down the vacancy posting cost. For the

moot. I default to including all earnings from temporary employment.

distribution of firm productivity, I choose an upper-truncated Pareto distribution with a tail parameter of unity (Zipf’s law; note that upper-truncation ensures that the mean and variance of productivity remain finite). The truncation point \bar{z} is disciplined by the average (self-reported) annual growth rate for firms in the Enterprise Survey — a higher \bar{z} directly corresponds to a higher average growth rate due to the fact that more productive firms grow faster.

4.3. Model Validation and the Experiment of Abebe et al. (2021a)

One possibility, absent from discussion so far, is that the intuition embedded in the model that credit constraints are a substantial driver of low levels of search is simply not true. If this were the case, it would be difficult to put any stock in the model’s conclusions for optimal policy. To address this and test whether the model can explain observed search behavior, I replicate an experiment performed by Abebe et al. (2021a) in the model and perform model validation by comparing the model outcomes to the experimentally estimated outcomes. As mentioned above, it is important to note that while control outcomes from the experiment are used during model estimation, treatment outcomes and data are not. Thus comparing the model’s predicted treatment effects to those estimated in the experiment represents a valid “out-of-sample” test of the model.

This experiment took place in 2014-2015 and evaluated the effects of providing a cash subsidy covering some of the costs of job search to prospective searchers in Addis Ababa, Ethiopia. In the context of Addis Ababa, the majority of job search takes place in person in the city center. Thus the cost of travel (typically by minibus) to the city center represents a large and salient cost of job search.

The experiment sampled young individuals who “(i) were between 18 and 29 years of age; (ii) had completed high school; (iii) were available to start working in the next three months; and (iv) were not currently working in a permanent job or enrolled in full time education.” (Abebe et al. 2021a) and randomly offered some individuals cash that could be collected in person at the city center up to three times each week. While not literally a job search subsidy as individuals could theoretically travel to the city center, collect the cash, and leave without searching, doing so would be ineffective as the cost of the subsidy was not large enough to cover the full round-trip journey.²² Thus collecting the cash only makes sense if the

²²In fact, the authors ensure this by varying the subsidy offered to each individual based on the location, and thus minibus ticket cost, of the individual’s home. However, I abstract from this heterogeneity and model the subsidy as uniform at the median value of subsidy offered.

individual intended to travel to the city center for other purposes (presumably job search). The cash was available for 16 weeks after which treated individuals were 3.4 percentage points ($p < 0.1$) more likely to be employed in a permanent job.

One potential concern with using this experimental sample for model estimation is that it may not be representative of the broader labor market. In particular, if the sampling rules were designed to select marginal individuals who have the toughest time finding jobs and, presumably, the lowest return to wage work, one might expect that estimating the model based on these individuals, without adjusting for these sampling rules, would substantially understate the return to search. To determine whether this is an issue, I construct a representative sample of searchers in Addis Ababa using the 2018 LSMS (described above) and compare this to the experimental sample.

Appendix Table A.1 makes this comparison. At least in terms of basic observables, the experimental and representative samples appear similar. Individuals with less than a secondary education are the major exception — by construction there is no one without a secondary education in the experimental sample, but they make up 28 percent of the representative sample. Beyond this, the representative sample is slightly older (28 vs 23 years) and both samples possess a similar mix of secondary- and post-secondary-educated and similar male-female splits. We can go even further and leverage the fact that the gaps between LSMS waves (2018 to 2021) and between the experimental baseline and endline (2015 to 2018) both happen to be three years. This allows us to measure employment and earnings after three years in both samples. The samples also look similar on this front, with 54 percent of searchers reporting some form of employment three years later in both the experimental and representative samples. Conditional on employment, monthly earnings in the representative sample are slightly higher (2300 vs 1800 Birr) but are measured noisily, and I am unable to reject the possibility that earnings are identical across the two samples. Overall, the experimental sample appears to be a fairly representative sample of searchers. To the extent that there are differences (i.e. fewer searchers with less than a secondary education in the experimental sample), these differences suggest that the experiment overstates, rather than understates, the returns to search.

Replicating the Experiment: To replicate the experiment in the model, I select a representative but small (measure zero) subset of individuals not employed in the wage sector from the steady-state distribution of individuals. In this sense,

the outcomes of sampled individuals do not affect equilibrium outcomes, and the experiment happens in “partial equilibrium”. The sample is divided equally into treatment and control groups, and the cost of search parameter b is reduced by two-thirds (the median subsidy offered in the experiment) for the treatment group for 16 periods.

Experimental outcomes can then be observed by simulating the behavior of the treatment and control groups forward over time, and comparisons of means between the two groups correspond to Average Treatment Effects estimated by the experiment. For treatment households, I treat the experiment as an unanticipated MIT shock; households do not know ahead of time that they have been selected for treatment and cannot alter their behavior in response to such information (and are also fully aware that it will end after 16 periods). Thus differences between treatment and control groups before the treatment occurs are zero by construction.

Model vs Data: Figure 2 compares the model’s predictions for the increase in search behavior as a result of the subsidy to those observed in the data. The solid orange line depicts model predictions and the dotted red line depicts the experimentally estimated effects along with the associated 95 percent confidence interval. The model aligns with the experiment remarkably well. During the treatment period (between 0 and 16 weeks since treatment), treated individuals were roughly 5 percentage points more likely to search, a fact which is replicated in the model. There is a small decline in the point estimates in the last few weeks of treatment that is not quantitatively replicated by the model, but this is statistically insignificant, and the model continues to fall within the estimated 95 percent confidence interval.

The model also qualitatively replicates the fact that effects seem to persist for some weeks after treatment is ended, although the experimental point estimates here are noisy. The model’s predictions are quantitatively smaller than these point estimates, but are well within the 95 percent confidence interval. One explanation for the model’s underprediction of persistence is that the increase in search results in some sort of learning or habit formation, leading treated individuals to search more often even after the end of treatment, that is not captured in the model.

Even if the model accurately matches the increase in search behavior due to treatment, it may not match the increase in wage employment if, for example, search within a short time period exhibits substantial diminishing returns (i.e. job seekers first go after opportunities they judge most promising). Reflecting the im-

Figure 2: Treatment Effect on Search Behavior over Time: Data and Model

This figure displays the treatment effect on search behavior as a function of "weeks since treatment" in both the data and estimated model.

implicit assumption of constant returns, the model predicts a roughly 5 percentage point higher probability of being employed after 16 weeks, the same as the increase in search behavior. The experimental equivalent is 3.4 percentage points (90 percent confidence interval: 0.3 to 6.3). This is slightly lower, but the model is still reasonably accurate, and the 90 percent confidence interval does not rule out the assumption of constant returns.

I interpret the success of the model in predicting the response of worker search behavior to a search subsidy as evidence supporting (or, at least, failing to reject) the core idea that credit constraints are a substantial driver of search behavior.

5. Efficient Policy in the Estimated Model

With the estimated model in hand, we can now quantify the optimal feasible policy and investigate the relative sizes and contributions of the various externalities laid out in Section 3. The simplest way to accomplish this is to directly solve for the optimal tax/subsidy rates on search and self-employment, compute the resulting welfare gains, and then decompose the total impact of the policy across the various channels. Here it is important to note that while equations (22) – (24) in Proposition 2 were expressed under the simplification of linear utility (for clarity), the results in this section are computed using the estimated model which exhibits substantial curvature ($\sigma = 3.6$).

Table 3 reports the tax rates of the optimal policy (which, recall, consists of taxes on search and self-employment earnings subject to a balanced-budget constraint) as well as the impact of the policy on welfare and the size of the wage sector. Although there is some minor variation along the transition path after the policy is implemented, these rates correspond to the eventual rates in the post-policy steady-state.

The most surprising result is that the optimal tax rate on search is positive and large, increasing the cost of search by 50 percent of average self-employment earnings. In other words, the competitive equilibrium exhibits too much search, and the planner finds it necessary to discourage this through a tax that shrinks the size of the wage sector from 29 percent (of workers) to 16 percent. At least from the perspective of the model, the Crowd Out externality dominates, and more barriers to search need to be erected. The positive tax rate on search is mirrored by the negative tax rate on self-employment earnings (i.e. a subsidy) to comply with the balanced-budget constraint. This subsidy is moderate in size at about 2.5 percent

Table 3: Results of the Efficient Policy

Optimal Subsidies/Taxes			
Search Tax:	50%	Self-emp. Tax:	-2.5%
<hr/>			
Welfare:	+1.9%	Size of Wage Sector:	-13pp
(Self-employed):	+1.9%	(Pre-policy):	29%
(Employed):	+1.7%	(Post-policy):	16%

Note: This tables displays the search tax and self-employment subsidy rates that make up the optimal feasible policy in the estimated model, as well as the impact on welfare and the size of the wage sector that occurs when these rates are implemented. For ease of comparison, the "Search Tax" and "Self-emp. Tax" values are displayed in common units of "Percentage of Average Self-Employment Earnings". See text for details.

of average earnings.

The overall impact on welfare of the policy is substantial. Average welfare increases by 1.9 percent of consumption. This impact is not particularly regressive or progressive as the average impact among the self-employed and the average impact among the employed are similar (1.9 percent and 1.7 percent respectively). Although the employed pay more of the search cost, as they are more likely to search in the near future, they also reap more of the benefits from shrinking the Crowd Out externality. On the other hand, the self-employed largely benefit through higher earnings due to the subsidy.

5.1. Decomposing the Impact of the Externalities

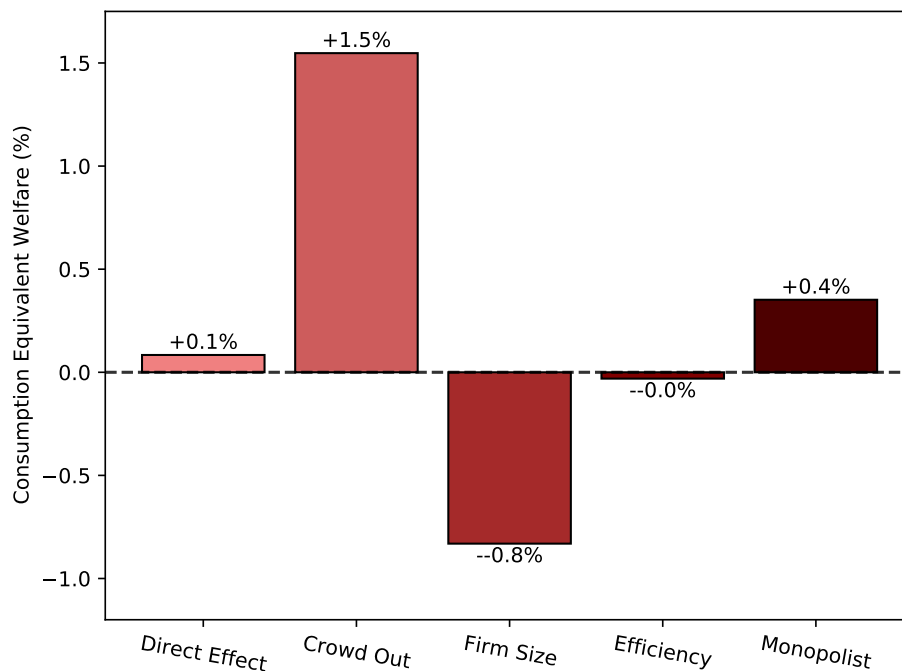

A natural way to examine an externality's individual contribution to the optimal policy is to marginally shrink the impact of that externality and re-examine the policy's impact.²³ For example, one could reduce the impact of Crowd Out by 10 percent by calculating how many more jobs would be created in the short-run if workers' private perceptions were correct and artificially increasing the number of jobs created by 10 percent of this. Computing the impact of the optimal policy under this adjustment and comparing to the policy's impact in the full model reveals

²³Computing contributions by marginally reducing a channel (rather than entirely eliminating it) is keeping in line with the fact that the planner in Proposition 2 equates the marginal costs and benefits of search and thus cares about the marginal impact of each externality.

Crowd Out’s contribution. That is, if the optimal tax leads to a 1.9 percent increase in welfare in the baseline model and a 1.8 percent increase after this adjustment is made, we can say that 1.0 percentage points (1.9 less 1.8 divided by 10 percent) of the policy’s welfare gains are attributable to Crowd Out.

Figure 3 displays the contribution of each of the externalities to the overall policy impact implied by this calculation. It also displays the change in welfare that occurs due to the fact that the optimal policy leads to minor changes in budget constraints (labeled “Direct Effect”; refer to subsection 3.3 for discussion). Because the optimal policy is a tax that reduces search, *negative* search externalities take on positive values, as they are the reason that the tax results in welfare gains. Similarly, positive externalities take on negative values.

Figure 3: Sources of Welfare Gains from Optimal Policy

Note: This figure displays the (marginal) contribution of each of the four externalities to the overall welfare impact of the optimal feasible policy. Refer to subsection 5.1 for details on how this decomposition is performed.

Both the Crowd Out and Firm Size externalities contribute substantially, accounting for +1.5 percent and -0.8 percent of the welfare gains respectively. Meanwhile, the Allocative Efficiency and Monopolist channels make much smaller contributions, accounting for -0.0 and +0.4 percent. Finally, the Direct Effect of the

policy on budgets accounts for a positive but small portion of the welfare gains, suggesting that the optimal policy under the restricted set of tax instruments is very close to what would be achieved without restrictions.²⁴

The upshot of this decomposition is that the result that the optimal policy is a tax on search, rather than a subsidy, is primarily driven by the large size of the Crowd Out effect. The marginal searcher generates substantially fewer jobs than they take (in the short run), and the increases in hiring and employment in the long run stemming from the relaxation of entrepreneurs' financial constraints are not large enough to offset this effect. As a result, the competitive equilibrium exhibits too much search, and the optimal policy corrects this.

5.2. Driving Forces

What features of the data drive the model to the conclusion that Crowd Out is so large? The answer comes from examining the equation for short-run job creation (18), rewritten here for convenience.

$$\underbrace{\frac{dm(S, V(S))}{S}}_{\text{Short-run Job Creation}} = \theta p(\theta) \left(\underbrace{\varepsilon_{m,S}}_{\text{Direct}} + \underbrace{(1 - \varepsilon_{m,S}) \frac{d \log V}{d \log S}}_{\text{Indirect}} \right) \quad (25)$$

This equation makes it clear that the aggregate response of firms' vacancy postings to an increase in search ($\frac{d \log V}{d \log S}$) is the primary driver of the size of Crowd Out. A large value (close to the upper bound of one) reflects a world where firms are highly responsive to increases in the number of searchers and the resulting declines in hiring costs. In this world, the marginal searcher creates many jobs as they induce a large increase in the number of vacancies (which create jobs) and Crowd Out is small. In contrast, a small value (close to the lower bound of zero) reflects a world where firms respond little to changes in the number of searchers and, as a result, the marginal searcher creates few jobs. In this world, Crowd Out is large.

In the model, the key determinant of firms' responsiveness turns out to be the vacancy posting cost c . If c is high, then hiring costs are large and the reduction in labor market tightness due to the marginal searcher represents a substantial reduction in a firm's total costs and frees up a substantial amount of resources

²⁴The fact that the contribution of each channel is computed by marginally, rather than totally, is the primary reason that summing the channels' contributions (+1.1 percent) does not yield the total welfare impact of the policy (+1.9 percent).

that can now be allocated towards growth and expansion. As a result, firm hiring and thus vacancy postings increase substantially. On the other hand, if c is small, this reduction only represents a small portion of total costs, and there is not much expansion.

In model estimation, c is estimated to match the fact that firms report that hiring an additional worker would cost roughly 120 percent of the average (weekly) wage paid by the firm. We can test the intuition above quantitatively by artificially increasing this value by 5x to 600 percent, re-estimating the model to match this new moment, and seeing how the optimal policy changes.²⁵

Performing this exercise confirms our intuition — in the re-estimated model, the optimal policy transforms from a 50 percent tax on search to a subsidy equal to about 25 percent of average self-employment earnings. In this alternative model, firms are substantially more responsive to changes in labor market tightness and the Crowd Out effect is substantially reduced. I interpret this as evidence that the fact that the model perceives hiring costs equal to 120 percent of average weekly wages to be “small” is the primary driver of its conclusion that the optimal policy is to tax search.

What about $\varepsilon_{m,S}$?: Another potentially important parameter, based on equation (18), is the matching function elasticity $\varepsilon_{m,S}$, which governs the relative importance of searchers and vacancies in the process of job creation. Even if firms do not respond to higher search by posting many additional vacancies, this may not lead to substantial Crowd Out if vacancies are unimportant in job creation (i.e. $\varepsilon_{m,S}$ is close to unity). Although the importance of this parameter is reminiscent of the classic congestion externality of Hosios (1990), the presence of the indirect short-run job creation term, as well as the long-run Firm Size and Allocative Efficiency effects, means that comparing this elasticity to workers’ bargaining share is no longer enough to determine whether the positive or negative externalities dominate.

We can do a quantitative experiment similar to the one we did for c above to test if our choice of value for $\varepsilon_{m,S}$ is important in driving our results. This is important as the aggregate matching elasticity is a hard-to-pin-down parameter, even in developed countries where there is substantially more data available (particularly regarding vacancy postings). In fact, the value of 0.3 used here is simply lifted from

²⁵ An increase of 5x to 600 percent is chosen as this is roughly the largest value at which the model can maintain a reasonable fit to the data.

Hall & Schulhofer-Wohl (2018) who estimate the elasticity in the United States. If the elasticity in Addis Ababa is substantially different and the optimal policy depends heavily on the chosen value, this presents a threat to the validity of the quantitative results.

Fortunately, this concern appears to be unfounded. Even dramatically varying the value of $\varepsilon_{m,S}$ between 0.1 and 0.8 (from a baseline of 0.3) has little impact on the optimal policy which remains a tax. The exact magnitude of the tax slightly varies from 60 percent (when $\varepsilon_{m,S} = 0.1$) to 30 percent (when $\varepsilon_{m,S} = 0.8$) but generally speaking remains very similar to the optimal tax of 50 percent of average self-employment earnings from the baseline parameterization. These results reinforce the conclusion that it is mostly firms' responsiveness to additional searchers, driven by whether hiring costs are large or small, that determines the optimal policy.

6. Alternative Policies

The results of the previous section indicate that the level of search is too high. Using the policy instruments implied by the constrained planner's problem, this corresponds to an optimal policy that taxes search. Such a policy may, however, be impractical and unfeasible. New taxes are politically unpopular and, even if they were not, it is not immediately clear how a search tax could be implemented — monitoring search behavior is difficult so any tax would have to rely on self-reporting, with little incentive to accurately report.

The purpose of this section, then, is twofold. First, I explore the optimality of alternative approaches to decreasing the level of search. Second, I pivot from normative to positive analysis and use the estimated model to study the impact of more commonly proposed policies. Here I focus in particular on the difference between partial equilibrium results — those that would be observed in an experimental settings — and general equilibrium results, following the spirit of the literature that uses macroeconomic models to interpret experiment results in a general equilibrium setting (e.g. Brooks, Donovan & Johnson 2020, Fujimoto, Lagakos & VanVuren 2023, Lagakos, Mobarak & Waugh 2023). In both cases, I show that the lessons from the constrained planner problem above remain relevant even in these alternative settings, reinforcing the importance of my results.

6.1. Optimal Self-Employment Subsidies

If taxing searchers is not feasible, the level of search can also be reduced purely by subsidizing self-employment without any tax on search. Such a policy is feasible and likely to have much more political support than a search tax; however, unlike the optimal policy above, which is restricted to be budget neutral, a pure subsidy is costly. Thus in order to make sensible welfare comparisons, I consider the optimal self-employment subsidy policy to be the one that maximizes welfare *relative to* an equivalently costly universal lump-sum transfer (otherwise the optimal subsidy would be infinite as it extends the aggregate budget constraint).

Table 4: Optimal Self-Employment Subsidy vs Baseline Policy

Policy	SE Sub	Search Tax	Net Cost	% U Rate	Welf.
Only Subsidy	20%	0%	16.5% GDP/cap	6.7%	+ 2.7%
Baseline	2.5%	50%	0% GDP/cap	6.6%	+1.9%

Note: This table compares the baseline optimal policy with the optimal self-employment subsidy. The first grouping of numbers compares the policies themselves while the second grouping of numbers compares their outcomes.

Table 4 displays the optimal self-employment subsidy and compares it to the baseline optimal policy of Section 5. The results are encouraging. Most notable is the fact that the optimal level of search, as summarized by the unemployment rate, is essentially identical to that of the baseline optimal policy (6.7% vs 6.6%). In other words, the overall quantitative conclusions taken from the baseline policy exercises seem to generalize to this alternative setting under a different set of policy tools rather than being relevant only to the precise set of tools implied by the constrained planners problem. This is an important result, given the potential practical difficulties in implementing the baseline policy discussion above.

The remaining results in Table 4 are less surprising. Implementing the optimal level of search using only a self-employment subsidy requires a larger subsidy than when a search tax can also be leveraged and is fairly expensive at over 16 percent of average earnings. The resulting welfare gains are slightly larger than the baseline policy, arising from the fact that the self-employment subsidy is somewhat redistributive relative to the lump-sum transfers against which it is compared.

6.2. Subsidies in Partial and General Equilibrium

Here I use the model to evaluate what would happen if one were to ignore the general equilibrium search externalities outlined above and implement a subsidy to search anyways. I focus on a subsidy that reduces search costs by two-thirds (identical to the experiment used in model estimation) funded by a tax on wage workers. The justification for such a policy is natural — it helps to “complete” credit markets as searchers face borrowing constraints and lack any mechanism through which the income of future employment can be used to fund search today. Table 5 displays the results of this policy, focusing on the difference between partial and general equilibrium.

Table 5: Result of Search Subsidies

Model	Wage Sector	Welfare
Baseline	30%	–
(1) Subsidy Only (Partial Eq.)	42%	+3.7%
(2) Subsidy + Tax (Partial Eq.)	38%	+1.3%
(3) Subsidy + Tax (General Eq.)	33%	+0.1%
(4) Subsidy to Self-Emp. + Tax (GE)	26%	+1.5%

Note: This table displays the impact of implementing a subsidy for job search on the size of the wage sector and average welfare in the estimated model. Refer to the text for details on the models represented by each row.

In partial equilibrium, where job finding rates and wages are fixed, offering the search subsidy leads to substantial improvements in welfare (+3.7 percent of consumption) and a large increase in the size of the wage sector (from 30 to 42 percent). These large increases stem from the promising experimental results used to estimate the model — the wage sector exhibits a significant wage premium and providing a subsidy leads to a large increases in search behavior, suggesting that workers who would otherwise substantially benefit from wage work are credit-constrained away from search. Though the experiment corresponds to the externally funded case in (1), these same conclusions survive even when policy is internally funded via a tax on wage workers (row 2).

General equilibrium, however, tells a different story, and the policy looks much less effective in row (3). After accounting for changes in the job finding rate and wages (and the corresponding externalities that arise), the wage sector grows only by a very small amount (from 30 to 33 percent), and the welfare gains are substantially diminished (+0.1 percent). Though the welfare gains are still positive, this arises only due to the fact that the benefits of the redistributive component of the policy, which transfers income from wealthy wage earners to comparatively poor searchers, are enough to outweigh the welfare costs of moving further from the optimal level of search.

Building on the results of Section 5, we can explore a better policy. If redistributing from wage earners to searchers is highly valuable but carries a welfare cost due to inefficiently increasing the level of search, we can do even better by instead using these tax revenues to subsidize self-employment. This achieves nearly the same amount of redistribution with the added benefit of moving the equilibrium closer to efficiency. The results of this policy (using the same sized tax on wage earners and redistributing all revenue evenly to the self-employed) are displayed in row (4) and confirm this intuition. Welfare increases by 1.5 percent, over an order of magnitude more than the search subsidy.

Overall, this section shows that promising experimental (partial equilibrium) results for search subsidies do not guarantee that a policy will be successful when scaled-up to a general equilibrium level. Interestingly, these results also provide further insight into why the optimal policy within the model is to tax search. In particular, it is *not* because the model concludes that there are few workers who would gain substantially from wage work but are constrained and unable to search — the partial equilibrium results show that there are many such workers. Instead, it is a result of the fact that a search subsidy is ineffective at reducing these constraints due to the dominance of the Crowd Out effect. Although a subsidy does reduce the per-period cost of search, this is mostly offset by a decline in the job-finding probability. As a result, the average total cost of finding a job changes very little.

7. Conclusion

Many policies and interventions aim to expand the wage sector by increasing the extent to which (potential) workers can search for jobs. This paper develops and estimates a model that incorporates key features of developing countries in

order to understand and quantify the search externalities that arise in this setting. Contrary to the intuition that search should be encouraged, the estimated model suggests that the optimal policy is a substantial tax that increases the cost of search. The primary reason for this conclusion is that hiring costs do not appear to be a substantial constraint to firm growth and consequently, firms do not substantially increase vacancy postings in response to higher levels of search. As a result, the negative Crowd Out externality of search is larger than the positive Firm Size and Allocative Efficiency externalities — the marginal searcher generates few jobs and lowers the probability that other searchers find work.

One broad takeaway of the model and ensuing quantitative analysis, relevant to policymakers and economists alike, is that policies aimed at assisting job seekers should be very careful to distinguish between the extent to which policies encourage search (i.e. increase an individual's incentive or ability to search) and the extent to which they improve the effectiveness of search (i.e. improve the productivity of the matching function), as improvements in search efficiency are not subject to the concern of crowding out. Because many policies represent a combination of these two effects (e.g. government subsidies for employment agencies, discussed in [Wu & Wang 2023](#), may encourage search by lowering the price of this service but may also improve efficiency if agencies are able to effectively streamline the matching process), experimental evaluations of these policies can productively try to distinguish between their impact on each.

The quantitative conclusions of Sections 5 and 6 should be caveated by noting that the model is estimated to the specific setting of Addis Ababa. Although quantitative exploration reveals that it is fairly difficult (though not impossible) to overturn the conclusion that the optimal policy is a tax on search, the exact level of the optimal tax can vary substantially depending on the targeted moments. Applying the model in different settings would require new data on these moments, which may be difficult to find depending on the setting.

Appendix

A. Additional Tables and Figure

Table A.1: Summary Statistics of Experimental Sample vs LSMS

	LSMS Searchers	Experimental Sample
Less than Secondary	28%	0%
Secondary	41%	59%
Post-secondary	31%	41%
Female	52%	54%
Age (years)	28	23
After 3 years:		
Any work	54%	54%
Earnings (2018 Birr, monthly)	2318	1813

Note: This table displays summary statistics comparing the individuals selected into the experimental sample of [Abebe et al. \(2021a\)](#) to a representative sample of searchers constructed from the 2018 wave of the Ethiopia LSMS. Because earnings after 3 years for the LSMS sample are measured in 2021, these values are deflated to 2018 Birr using the World Bank's reported 201 percent cumulative consumer price inflation rate for Ethiopia from 2018 to 2021.

B. Derivations and Proofs from Section 2.5

The first result to show is that the entrepreneur's optimal choices of f' and n' in steady-state satisfy $\eta(z, \bar{\theta}) = \frac{\gamma f'^*}{n'^*}$ for some function η depending only on z and $\bar{\theta}$. Substituting in the wage determination equation (which the entrepreneur takes as given) and the vacancy posting constraint, the first-order condition for f' and n' can be combined with the envelope condition for f and n to generate

$$\begin{aligned} \beta \Delta \mu' \left((1 - \alpha)(1 - \chi) z \left(\frac{\gamma f'}{n'} \right)^\alpha - \left((1 - \chi) \underline{w} - \frac{c}{p(\theta(X'))} (1 - \lambda) \right) \right) &= \frac{c}{p(\theta(X))} \mu \\ \beta \Delta \mu' \left(\gamma \alpha (1 - \chi) z \left(\frac{\gamma f'}{n'} \right)^{\alpha-1} + 1 - \gamma(r + \delta) \right) &= \mu \end{aligned}$$

where μ is the Lagrange multiplier on the budget constraint and $\theta(X)$ is a price function that depends on the aggregate state X . Combining these two equations,

substituting in η , and defining A , $B(\theta(X), \theta(X'))$, and $C(\theta(X), \theta(X'))$ for clarity yields

$$Az\eta^\alpha + B(\theta(X), \theta(X'))z\eta^{\alpha-1} + C(\theta(X), \theta(X')) = 0 \quad (26)$$

which, for $0 < \alpha < 1$, can be shown to have a unique and positive solution for η for any value of z , X , and X' . Call this solution $\tilde{\eta}(z; X, X')$. Finally, substituting $\bar{\theta} = \theta(X) = \theta(X')$ and defining $\eta(z, \bar{\theta}) = \tilde{\eta}(z; \bar{\theta}, \bar{\theta})$ completes the derivation.

The next result to show is that an entrepreneur's growth rate is constant in steady-state, that is, that f'^* satisfies $f'^* = \hat{g}(z, \bar{\theta})f$ for some function g . This follows almost directly from the previous result. Substituting $n = \frac{\gamma}{\hat{\eta}(z, \bar{\theta})}f$ in to the budget constraint of the entrepreneur problem reveals that the RHS of the budget constraint is now linear in f and can be written

$$d + E(z, \bar{\theta})f' = D(z, \bar{\theta})f \quad (27)$$

for appropriately define functions $D(z, \bar{\theta})$ and $E(z, \bar{\theta})$ which depend only on z , $\bar{\theta}$, and parameters. Because entrepreneurs possess CRRA utility, the entrepreneur problem looks similar to a cake-eating problem has the well-known solution of a constant growth rate in f depending on the values of D and E (shown below), implying that that $f' = \hat{g}(z, \bar{\theta})f$ for some function \hat{g} .

The final step is to provide the derivations for equations (16) and (17). Building on (27) and applying the solution to the cake-eating problem to find f'^* yields²⁶

$$\begin{aligned} \hat{g}(z, \bar{\theta}) &= \left(\beta \Delta \frac{D(z, \bar{\theta})}{E(z, \bar{\theta})} \right)^{\frac{1}{\sigma}} \\ &= \left(\beta \Delta \frac{((1 - \chi)\gamma z \hat{\eta}(z, \bar{\theta})^{\alpha-1} - ((1 - \chi)\underline{w} - \frac{c}{p(\bar{\theta})}(1 - \lambda))\frac{\gamma}{\hat{\eta}(z, \bar{\theta})} + (1 - \gamma(r + \delta)))}{(1 + \frac{c}{p(\bar{\theta})}\frac{\gamma}{\hat{\eta}(z, \bar{\theta})})} \right)^{\frac{1}{\sigma}} \end{aligned}$$

The chain rule yields $\frac{d\hat{g}}{d\bar{\theta}} = \frac{\partial \hat{g}}{\partial c/p(\bar{\theta})} \frac{dc/p(\bar{\theta})}{d\bar{\theta}} + \frac{\partial \hat{g}}{\partial \hat{\eta}} \frac{d\hat{\eta}}{dc/p(\bar{\theta})} \frac{dc/p(\bar{\theta})}{d\bar{\theta}}$. Using either direct calculation of partial derivatives or implicit differentiation (in the case of $\frac{d\hat{\eta}}{dc/p(\bar{\theta})}$), we

²⁶While this solution to a “generalized cake eating problem” is straightforward, I have been unable to locate this exact formulation of the problem anywhere. As such, a derivation is available upon request.

can express each individual piece as

$$\begin{aligned}\frac{\partial \hat{g}}{\partial c/p(\bar{\theta})} &= -\frac{1}{\sigma} \hat{g}^{1-\sigma} \left(\frac{(\frac{\hat{g}}{\beta\Delta} - 1) + \lambda}{\frac{\eta}{\gamma} + \frac{c}{p(\bar{\theta})}} \right) \leq 0 \\ \frac{\partial \hat{g}}{\partial \hat{\eta}} &= \frac{1}{\sigma} \hat{g}^{1-\sigma} \left(\frac{\frac{\beta\Delta}{\hat{g}} - \frac{\hat{g}}{\beta\Delta}}{\frac{\eta}{\gamma} + \frac{c}{p(\bar{\theta})}} \right) \leq 0 \\ \frac{d\hat{\eta}}{dc/p(\bar{\theta})} &= \frac{\gamma(\alpha(1-\chi)z\hat{\eta}^{\alpha-1} - (r+\delta)) + \lambda}{J(\bar{\theta})} > 0\end{aligned}$$

where $J(\bar{\theta})$ is a placeholder for a complex but unambiguously positive expression (note that the second expression is simplified using the first order condition for f').

It is worth commenting briefly on why the claimed inequalities hold. Both the first and second inequalities follow directly from the fact that an optimizing entrepreneur will ensure that $g \geq \beta\Delta$ (an entrepreneur can always choose to select $k = 0, n = 0$ and simply eat their cake, yielding $g = \beta\Delta$, so this acts as a lower bound on all growth rates). The final expression follows from the fact that the presence of a collateral constraint ensures that the marginal product of capital ($\alpha(1-\chi)z\hat{\eta}^{\alpha-1}$) is always larger than the marginal cost of capital ($r + \delta$).

Returning to the main results and noting that $\frac{dc/p(\bar{\theta})}{d\theta} > 0$ by assumption, combining these inequalities with the chain rule shows that $\frac{d\hat{g}}{d\theta} < 0$ and $\frac{d\hat{\eta}}{d\theta} > 0$.

C. Derivations and Proofs from Section 3

First, I formally define the functions v and H introduced in equation (21).

$$\begin{aligned}v(m_t, \eta_t, \eta_{t+1}, g_t) &= \frac{1}{p(\theta)} \int [g_t(z) \Delta \frac{\eta_t(z)}{\eta_{t+1}(z)} - (1 - \tilde{\lambda})] \int m_t(a, z) da + \\ &\quad + \frac{\hat{D}(z, \theta_t, \eta_t(z)) \gamma f}{\eta_{t+1}(z)} h(z) dz\end{aligned}\tag{28}$$

$$\tag{29}$$

$$H(z, m_t, \eta_t, \eta_{t+1}, g_t) = \frac{[g_t(z) \Delta \frac{\eta_t(z)}{\eta_{t+1}(z)} - (1 - \tilde{\lambda})] \int m_t(a, z) da + \frac{\hat{D}(z, \theta_t, \eta_t(z)) \gamma f}{\eta_{t+1}(z)} h(z)}{p(\theta) v(m_t, \eta_t, \eta_{t+1}, g_t)}\tag{30}$$

The expression for v simply aggregates vacancy postings across all previously existing firms (first term) and all newborn firms (second term). The expression for H

computes the number of new hires matched to a z -type entrepreneur (numerator) and divides by total number of new hires (denominator).

The problem of the constrained social planner is given sequentially by

$$\begin{aligned}
& \max_{\{c_t, a'_t, s_t, \theta_t, m_t\}_{t=0}^{\infty}} \sum_{t=0}^{\infty} \beta^t \int \int \int u(c_t) m_t(a, z) j(y) dy da dz \\
& \text{s.t. } a'_t + c_t = Ra + (1 - s_t)y + s_t(w_t(z) - (1 - z)b) \quad \forall a, y, z \\
& \quad a_{t+1} \geq 0 \\
& \quad s_t(a, z) \in \{0, 1\} \\
& \quad \frac{v(m_t, \eta_t, \eta_{t+1}, g_t)}{\theta_t} = \int \int s_t(a, 0) m_t(a, 0) j(y) dy da \\
& \quad m_{t+1}(a'_t, 0) = m_t(a, 0) - \theta_t p(\theta_t) \int s_t(a, 0) m_t(a, 0) j(y) dy \\
& \quad m_{t+1}(a'_t, z) = (1 - \tilde{\lambda}) m_t(a, z) + H(z, m_t, \eta_t, \eta_{t+1}, g_t) \theta_t p(\theta_t) \int s_t(a, 0) m_t(a, 0) j(y) dy
\end{aligned} \tag{31}$$

where the functions η_t and g_t arise from the slightly modified sequential problem of an entrepreneur:

$$\begin{aligned}
& \max_{\{d_t, f_{t+1}, k_t, n_t, v_t\}} \sum_{t=0}^{\infty} (\beta \Delta)^t \frac{c_t^{1-\sigma}}{1-\sigma} \\
& \text{s.t. } d_t + f_{t+1} = (1 - \chi) z k_t^\alpha n_t^{1-\alpha} - (r + \delta) k_t - (1 - \chi) \underline{w} n_t + f_t - c v_t \\
& \quad n_{t+1} = (1 - \lambda) n_t + p(\theta_t) v_t \\
& \quad k_t \leq \gamma f_t \\
& \quad f_0 \in \mathbb{R}
\end{aligned} \tag{32}$$

so that $\eta_t = \frac{\gamma f_t}{n_t}$ and $g_t = \frac{f_{t+1}}{f_t}$.²⁷ Note that here I have suppressed the initial condition of the planner's problem and imposed the scale-invariance of the entrepreneurs optimal capital-labor ratio and growth rate by leaving the initial condition f_0 arbitrary.

In analysis of the problem of the social planner, it will be useful to note that

²⁷Even here in the appendix I opt to write the planner's problem for the case of no autocorrelation in individuals' self-employment productivity (i.e. y is drawn from $j(y)$ each period). Including autocorrelation is conceptually simple and involves adjusting only the final two inequalities governing the evolution of the distribution m_t (and the integral in the objective function); however, doing so leads to prohibitively cumbersome notation and adds no additional insight.

while η_t and g_t are potentially functions of z and the entire sequence of labor market tightness $\{\theta\}_{t=0}^{\infty}$, solving the entrepreneur's problem reveals that they depend only on ability z and current and future tightness θ_t, θ_{t+1} and thus can be written as $\eta_t(z, \theta_t, \theta_{t+1})$ and $g(z, \theta_t, \theta_{t+1})$. The independence of entrepreneur policy functions from values of θ beyond period $t + 1$ follows directly from the linearity of the hiring cost, combined with the parameter assumptions that ensure that any operating entrepreneur will choose $v_t > 0$ each period. While the continuation value of an entrepreneurs labor force depends in theory on the whole sequence of labor market tightness, the ability to re-optimize at linear cost tomorrow ensures that this continuation value is equal to the "liquidation value" of the workforce next period.

C.1. Notes and Proof for Proposition 2

Proof: The first step is to rewrite the planner's problem to eliminate the binary choice of s_t which complicates analysis. It's fairly straightforward to show that, for utility functions exhibiting diminishing marginal utility, the optimal choice of s_t takes the form of a cutoff rule in a above which individuals search and below which they do not (this fact arises directly from the fact that c_t^* is monotonically increasing a conditional on s_t and diminishing marginal utility). Thus we can rewrite the planner's problem as selecting an optimal cutoff s_t , which is differentiable. I also rewrite the planner's problem in recursive form to simplify analysis.

$$\begin{aligned}
V(\theta_{-2}, \theta_{-1}, m) &= \max_{c, a', s, \theta, m'} \int \int \int u(c) m(a, z) j(y) dy da dz + \beta V(\theta_{-1}, \theta, m') \\
s.t. \quad a' + c &= Ra + (1 - \text{St}(a - s))y + \text{St}(a - s)(w(z) - (1 - z)b) \quad \forall a, y, z \\
a' &\geq 0 \\
\frac{v(m, \eta, \eta', g)}{\theta} &= \int_s^\infty m(a, 0) da \\
m'_e(a', 0) &= \int \tilde{\lambda} m(a, z) dz \\
m'_u(a', 0) &= m(a, 0) - \text{St}(a - s)\theta p(\theta)m(a, 0) \\
m'_e(a', z) &= (1 - \tilde{\lambda})m(a, z) \\
m'_u(a', z) &= H(z, m, \eta, \eta', g)\text{St}(a - s)\theta p(\theta)m(a, 0) \\
m'(x, 0) &= m_e(x, 0) + m_u(x, 0) \\
m'(x, z) &= m_e(x, z) + m_u(x, z)
\end{aligned} \tag{33}$$

where $\text{St}(x)$ is the step function defined via the integral of Dirac's delta δ_x .

Because the state variable describing the distribution of agents across states m is a function $\mathbb{R}^2 \rightarrow \mathbb{R}$, the value function V is technically a functional and making progress requires dipping into functional analysis. I keep things relatively simple and try to align notation as closely as possible to what is typical in more standard situations. To this end, define the following shorthand to capture the notion of a “derivative of y with respect to the value of m at point (a, z) ”:

$$\frac{dy}{dm(a, z)} \equiv \left. \frac{d}{d\epsilon} y(m + \epsilon \delta_a \delta_z) \right|_{\epsilon=0}$$

With this defined, we can proceed.

The first order condition with respect to s yields

$$\frac{\lambda(s, 0)}{m(s, 0)}(s + b) = \theta p(\theta) \left(\int \mu(s, z) H(z) dz - \mu(s, 0) \right) + \tau \tag{34}$$

where λ and τ are the Lagrange multipliers on the budget and theta constraints respectively. We can then generate a pair of envelope conditions with respect to $m(s, z)$ and $m(s, 0)$ (note that I have used the first order condition for s to eliminate

τ from both).

$$\begin{aligned} \frac{1}{m(s, z)} \frac{dV}{dm(s, z)} &= \int u(c)j(y)dy + \left(g(z)\Delta\frac{\eta}{\eta'} - (1 - \tilde{\lambda})\right) \left(\int H(z)\mu(s, z)dz - \mu(s, 0)\right) \\ &\quad - \frac{\lambda(s, 0)}{\theta p(\theta)m(s, 0)}(s + b) \left(g(z)\Delta\frac{\eta}{\eta'} - (1 - \tilde{\lambda})\right) + \tilde{\lambda}\mu(s, 0) \\ &\quad + (1 - \tilde{\lambda})\mu(s, z) + \left(g(z)\Delta\frac{\eta}{\eta'} - (1 - \tilde{\lambda})\right)(\tilde{\omega}_1 - \tilde{\omega}_2) \end{aligned} \quad (35)$$

$$\frac{1}{m(s, 0)} \frac{dV}{dm(s, 0)} = \int u(c)j(y)dy + \mu(s, 0) + \lambda(s, 0)(s + b) \quad (36)$$

where $\mu(a, z)$ and $\mu(a, 0)$ are the Lagrange multiplier on the constraints governing the evolution of m' and $(\tilde{\omega}_1, \tilde{\omega}_2)$ are defined in the discussion at the end of this section.

We can then use these conditions to generate an expression for $\int H(z) \frac{1}{m(s, z)} \frac{dV}{dm(s, z)} dz - \frac{1}{m(s, 0)} \frac{dV}{dm(s, 0)}$ which should be interpreted as the planner's increase in value from moving one (normalized) unit of workers into employment while obeying the constraint that fraction $H(z)$ of workers must be matched with an entrepreneur of productivity z .

We also have from the first order conditions on $m'(s, z)$ and $m'(s, 0)$ ²⁸

$$\int H(z)\mu(s, z)dz - \mu(s, 0) = \beta \left(\int H(z) \frac{1}{m(s, z)} \frac{dV}{dm'(s, z)} dz - \frac{1}{m(s, 0)} \frac{dV}{dm'(s, 0)} \right) \quad (37)$$

Combining this expression with the expression for the RHS referenced above, restricting to steady-state, and solving for the desired quantity yields

$$\int H(z)\mu(s, z)dz - \mu(s, 0) = \frac{\beta \int \int H(z)(u(c_z) - u(c_0))j(y)dydz}{1 - \beta \int H(z)g(z)\Delta dz} + \text{Drift Terms} \quad (38)$$

where c_z and c_0 are notation-saving shorthand for $c(a, z, y)$ and $c(a, 0, y)$ respectively, and the drift terms are discussed further below. This term can be plugged directly in to the first order condition with respect to s .

²⁸This phrase should be interpreted as intuitive shorthand for the first order conditioned generated by examining a delta-perturbation of m' at (a, z) i.e. $\frac{d\mathcal{L}}{dm'(a, z)}$ in the shorthand defined above.

With the hard part done, all that remains is to use the first order condition for θ to find the following expression for τ :

$$\begin{aligned} \tau = & \frac{\theta / \int_s^\infty m(a, 0) da}{\frac{d \log v}{d \log \theta} - 1} \left(\underbrace{\left(1 + \frac{d \log p}{d \log \theta} \right) \int_s^\infty \left(\int H(z) \mu(a, z) dz - \mu(a, 0) \right) m(a, 0) p(\theta) da}_{\text{Crowd Out}} \right. \\ & + \underbrace{\int \int \int \lambda(a, z, y) \frac{dw}{d\theta} j(y) dy dz da}_{\text{Monopolist}} + \underbrace{\theta p(\theta) \int_s^\infty \int \frac{dH(z)}{d\theta} \mu(a, z) dz m(a, 0) da}_{\text{Allocative Efficiency}} \left. \right) \quad (39) \\ & + \underbrace{\beta \frac{dV}{d\theta_{-1}}}_{\text{Anticipation}} \end{aligned}$$

where the effects of anticipation are captured in $\frac{dV}{d\theta_{-1}}$

Finally, plugging everything in to the first order condition for s shows that the planner assigns an individual in state $(a, 0)$ to search if and only if

$$u'(c_0)(y + b) \leq \beta \theta p(\theta) \frac{\int \int H(z) (u(c_z) - u(c_0)) j(y) dy dz}{1 - \beta \underbrace{\int H(z) g(z) \Delta dz}_{\text{Firm Size}}} + \text{Drift Terms} + \tau \quad (40)$$

The exact formulation of the decision rule used in Proposition 2 can be found simply by letting $\sigma \rightarrow 0$ and noting that the drift terms collapse to zero in this limit, concluding the proof.

Discussion of Drift Terms: The drift terms in the planner's decision rule serve as adjustments for the fact that the marginal job-seeker has a different level of asset holdings than the average job-seeker and, similarly, that the marginal newly employed individual has different assets than the average employed individual. Essentially, they adjust for the fact that the asset level of searchers will "drift" away

from s over time.

$$\begin{aligned}\text{Drift Terms} &= \frac{\left(1 - \frac{\int_s^\infty m(a,0)da}{m(s,0)}\right)\lambda(s,0)(y+b) + \left(g(z)\Delta\frac{\eta}{\eta'} - (1 - \tilde{\lambda})\right)(\tilde{\omega}_1 - \tilde{\omega}_2)}{1 - \beta \int H(z)g(z)\Delta dz} \\ \tilde{\omega}_1 &= \int \frac{\int m(a,z)\mu(a,z)\text{St}(a-s)m(a,0)da}{m(s,z)\mu(s,z)m(s,0)}dz \\ \tilde{\omega}_2 &= \int \frac{\int \int (g(x)\Delta - (1 - \tilde{\lambda}))H(x)m(a,x)\mu(a,x)\text{St}(a-s)m(a,0)dadx}{(g(z)\Delta - (1 - \tilde{\lambda}))m(s,z)\mu(s,z)m(s,0)}dz\end{aligned}$$

To see this, note that the drift terms collapse to zero when the distribution of asset holdings among both the employed and unemployed are concentrated at s (i.e. $m(a,z) = \delta_s m$ and $m(a,0) = \delta_s(1 - m)$). Further analysis of this term is possible but involves substantial technical complication (due to the necessity of tracking the evolution of assets over time) and provides very little additional insight.

No (Additional) Externalities in Savings Decision: Here I sketch the argument/proof of the fact that the presence of search does not induce an externality in individuals' savings decisions. That is, individuals facing taxes/subsidies aligning their privately optimal search decision rule with that of the planner will choose the same savings policy function as the planner.

The approach follows that of [Davila et al. \(2012\)](#) and leverages a change of variables in the planner's objective function from time-space to individual-space for any finite (N period) optimization sub-problem. Consider the sub-problem of a planner facing a distribution of agents m and who has already settled on the two-period-ahead policy function a'' but must decide today's policy function a' . One could consider the maximization of the sum of today's utility (averaged over m) and tomorrow's utility (averaged over the appropriately defined m'); this is the period approach and is how the planner's problem in (31) is written. One could alternatively consider the maximization of the *two period* utility for all agents alive in the first period (i.e. averaged over m) — the individual approach. These two objects are different ways of computing the same quantity.

The approach above lets us consider the following optimization problem:

$$\begin{aligned} \max \int \int & \left(\int u(Ra - \text{Inc}(y, a, s, z) - a')j(y)dy \right. \\ & \left. + \beta \mathbb{E} \left[\int u(Ra' - \text{Inc}(y, a', s', z') - a'')j(y)dy | s, z \right] \right) m(a, z) da dz \quad (41) \\ \text{Inc} = & (1 - \text{St}(a - s))y + \text{St}(a - s)(w(z) - (1 - z)b) \end{aligned}$$

Note that all the transition dynamics across employment states z are implicit in the expectations operator (a rigorous proof would require fully specifying these details, but they can be ignored in a proof sketch).

Taking the first order condition for a' from this problem reveals that it is identical to that derived from the individual problem. Of course these first order conditions contain the policy function for s , but the assumption that the search subsidy/tax implements the planner's search policy in the decentralized economy ensures that these functions are identical. Thus the savings policies are identical, and the proof sketch is complete.

Individual's Search Decision Rule: As was the case for the planner's problem, it is easy to show that individual's search decision rule is monotonic in their assets and thus the binary search choice in the individual problem can be replaced by the choice of an asset cutoff s above which the individual will search and below which they will not. Restating the relevant portion of the individual problem (5) for convenience (with auto-correlation in y removed and the aggregate state X suppressed):

$$\begin{aligned} V_u(a) = \max_{c, a', s} & u(c) + \beta \left((1 - \text{St}(a - s)\theta p(\theta)) E_y[V_u(a')] + \text{St}(a - s)\theta p(\theta) (E_z[V_e(a', z)]) \right) \\ V_e(a, z) = \max_{c, a'} & u(c) + \beta \left((1 - \tilde{\lambda}) V_e(a', z) + \tilde{\lambda} E_y[V_u(a')] \right) \\ \text{s.t. } & a' + c = (1 + r)a + (1 - \text{St}(a - s))y - \text{St}(a - s)b \text{ for } V_u \\ & a' + c = (1 + r)a + w(z) \text{ for } V_e \end{aligned}$$

The first-order condition for s then yields

$$u'(c_u)(y + b) = \beta \theta p(\theta) (E_z[V_e(a'_u, z)] - E_y[V_u(a'_u)]) \quad (42)$$

where c_u and a'_u denote the policy functions of the “unemployed” with their dependence on (a, y) suppressed. Plugging the policy functions into the value functions above and doing some careful rearranging to the RHS yields the policy rule for search.

$$u'(c_u)(y + b) \leq \beta \theta p(\theta) \frac{E_z[u(c_e)] - E_y[u(c_u)]}{1 - \beta(1 - \tilde{\lambda})} + \text{Drift Terms}$$

$$\begin{aligned} \text{Drift Terms} &= \beta(1 - \tilde{\lambda})\Delta_{a'_e, a'_u} - \Delta_{s, a'_u} + \beta(E_y[V_u(a'_e)] - E_y[V_u(a'_u)]) \\ \Delta_{x, y} &= (E_z[V_e(x)] - E_y[V_u(x)]) - (E_z[V_e(y)] - E_y[V_u(y)]) \end{aligned} \quad (43)$$

As in the planner’s problem, the inclusion of curvature in the utility function induces some “drift terms” that account for the fact that individuals’ savings drift away from the cutoff s over time.

It turns out that the drift terms in the privately optimal decision rule (43) and equivalent to the drift terms in the planner’s decision rule (40) in the sense that both terms yield the same value when given the same policy function a' . This is not particularly surprising, as both terms simply exist to adjust for curvature in the utility function. The powerful implication of this fact is that the externalities contained in τ above (as well as the difference in discount rates) make up an exhaustive list of wedges between the privately and publicly optimal decision rules, even with curvature in the utility. Formally showing this equivalence is somewhat cumbersome; the quickest approach involves an awkward change-of-variables in the planner’s problem (to make it look more like the individual’s problem) and can be provided upon request.

C.2. Positive Weight on Entrepreneurs’ Welfare

The results above all depend on the assumption that the planner places zero weight on the welfare of entrepreneurs. It is not too difficult to generalize this assumption and allow the planner to place arbitrary Pareto weight on entrepreneurs’ utility. Doing so requires the planner to track the distribution of entrepreneurs over their individual states. When approaching this in a fully general manner (i.e. tracking this distribution via a pdf m_e), the fact that the model is written in discrete time and the fact that entrepreneurs face no uncertainty combine to generate some technical unpleasantness — the distribution of entrepreneurs becomes “concentrated” at many points (i.e. there are point masses of z -entrepreneurs with collateral \underline{f} and

at $g(z, \theta)f$ with nothing in between).

While this can be handled via Dirac's delta, it is much simpler to directly impose the fact that the entrepreneur states evolve discretely. To that end, define $\{f_{t,\tau}(z)\}_{\tau=0}^{\infty}$ to be the collateral of a z -type entrepreneur born in period $t - \tau$ (which is identical for all z -types as their problem is deterministic conditional on survival) and $\{\hat{m}_{t,\tau}(z)\}_{\tau=0}^{\infty}$ to be the number of such entrepreneurs alive. From the planner's perspective, all necessary entrepreneur behavior can be inferred from these two sequences, making these the additional state variables required to generalize the problem.

The planner's objective function then becomes

$$\max \sum_{t=0}^{\infty} \beta^t \int \int \int u(c_t) m_t(a, z) j(y) dy da dz + \Lambda \sum_{t=0}^{\infty} \beta^t \int \sum_{\tau=0}^{\infty} u(d_{t,\tau}(z)) dz \quad (44)$$

where Λ is the relative weight on entrepreneurs' welfare. This can be written recursively as

$$\begin{aligned} V(\theta_{-2}, \theta_{-1}, m) + \Lambda V_E(\theta_{-2}, \theta_{-1}, f_{\tau}, \hat{m}_{\tau}) = \\ \max \int \int \int u(c) m(a, z) j(y) dy da dz + \Lambda \sum_{\tau=0}^{\infty} \int u(d_{\tau}(z)) m_{\tau}(z) dz \\ + \beta V(\theta_{-1}, \theta, m') + \Lambda \beta V_E(\theta_{-1}, \theta, f'_{\tau}, \hat{m}'_{\tau}) \end{aligned} \quad (45)$$

The additional constraints are

$$d_{\tau}(z) = F(z, \eta, \theta) f_{\tau}(z) \quad (46)$$

$$f'_{\tau+1}(z) = g(z, \eta, \theta_{-1}, \theta) f_{\tau}(z) \quad (47)$$

$$m_{\tau+1}(z) = \Delta m_{\tau}(z) \quad (48)$$

$$f'_0(z) = \left(\frac{1}{1 + \frac{c}{p(\theta)} \frac{\gamma}{\eta_i(z, \theta_{-1}, \theta)}} \right) f \quad (49)$$

$$m'_0(z) = M h(z) \quad (50)$$

where F is the multiple of collateral consumed by the entrepreneur each period ($F = (D - E(\beta \Delta \frac{D}{E})^{\frac{1}{\sigma}})$) for D, E as defined in (27).

Examining the new objective functions and constraints, it is clear that values of Λ greater than zero will the only change the planner's optimal search policy

through the appearance of new terms in the first-order condition for θ given in (39) as the search cutoff s appears nowhere in the new objective function or constraints. These new terms, which represent new search externalities, are given by

$$\sum_{\tau=0}^{\infty} \int \lambda_c(\tau, z) \frac{dF}{d\theta} f_{\tau}(z) dz + \sum_{\tau=0}^{\infty} \int \lambda_f(\tau, z) \frac{dg}{d\theta} f_{\tau}(z) dz + \int \lambda_f(0, z) \frac{dG}{d\theta} f dz \quad (51)$$

$$\frac{1}{G} = 1 + \frac{c}{p(\theta)} \frac{\gamma}{\eta_t(z, \theta_{-1}, \theta)} \quad (52)$$

where G is the (inverse) price of one “production unit” (i.e. one unit of collateral and $\frac{\gamma}{\eta}$ units of labor).

Using the first-order and envelope conditions arising from the new constraints and rearranging allows us to express these terms in steady-state as

$$\begin{aligned} & \Lambda \sum_{\tau=0}^{\infty} \int \left(\underbrace{u'(\bar{d}_{\tau}) \frac{dF}{d\theta}}_{\text{Current consumption change}} + \underbrace{\sum_{i=0}^{\infty} (\beta \bar{g})^i u'(\bar{d}_{\tau+i}) \frac{dg}{d\theta}}_{\text{Future consumption changes}} \right) \bar{f}_{\tau} \bar{m}_{\tau} dz + \\ & + \underbrace{\Lambda \beta \left(\sum_{\tau=0}^{\infty} \int (\beta \bar{g})^{\tau} u'(\bar{d}_{\tau}) \bar{m}_{\tau} \right) \frac{dG}{d\theta} f}_{\text{Initial reoptimization of newborns}} \end{aligned} \quad (53)$$

where I have suppressed the dependence of many outcomes on z for legibility. The first two terms correspond to changes in consumption for living entrepreneurs, both in the current period (due to changes in the multiple of collateral that is consumed F) and in future periods (due to changes in the growth rate g). The last term corresponds to the change in lifetime consumption for newborn entrepreneurs arising from changes in the price of one production unit (i.e. one unit of f and $\frac{\gamma}{\eta}$ units of labor) which impacts lifetime consumption by changing entrepreneurs' initial size.

These terms all depend on the response of the appropriate object (F, g, G) to the change in θ . With a slight abuse of notation we can use the chain rule to separate these changes into those that occur due to changes in the optimal capital-labor ratio η and those that do not via $\frac{dF}{d\theta} = \frac{\partial F}{\partial \theta} + \frac{\partial F}{\partial \eta} \frac{\partial \eta}{\partial \theta}$ where the first partial derivative is taken while holding η (which depends on θ) constant. The expression in (53) can then be split into two terms, one depending on θ and one depending on η .

$$\Lambda \underbrace{\left(\sum_{\tau=0}^{\infty} \int (u'(\bar{d}_{\tau}) \frac{\partial F}{\partial \theta} + \sum_{i=0}^{\infty} (\beta \bar{g})^i u'(\bar{d}_{\tau+i}) \frac{\partial g}{\partial \theta}) \bar{f}_{\tau} \bar{m}_{\tau} dz + \beta \left(\sum_{\tau=0}^{\infty} \int (\beta \bar{g})^{\tau} u'(\bar{d}_{\tau}) \bar{m}_{\tau} \right) \frac{\partial G}{\partial \theta} \underline{f} \right)}_{\text{Market Thickness}} + \quad (54)$$

$$\Lambda \frac{\partial \eta}{\partial \theta} \underbrace{\left(\sum_{\tau=0}^{\infty} \int (u'(\bar{d}_{\tau}) \frac{\partial F}{\partial \eta} + \sum_{i=0}^{\infty} (\beta \bar{g})^i u'(\bar{d}_{\tau+i}) \frac{\partial g}{\partial \eta}) \bar{f}_{\tau} \bar{m}_{\tau} dz + \beta \left(\sum_{\tau=0}^{\infty} \int (\beta \bar{g})^{\tau} u'(\bar{d}_{\tau}) \bar{m}_{\tau} \right) \frac{\partial G}{\partial \eta} \underline{f} \right)}_{\text{Capital Shallow}} \quad (55)$$

This, finally, is the most intuitive expression of the additional externalities that emerge when putting positive weight on entrepreneurs' welfare.²⁹ The first term, labeled "Market Thickness", captures the logic of the textbook market thickness externality. When search increases (and thus θ decreases) and the cost of hiring a worker declines, entrepreneur resources are freed up which increase consumption through a variety of channels. Lower hiring costs mean that entrepreneurs can consume a larger multiple of their collateral each period as fewer profits must be allocated towards hiring for a given growth rate ($\frac{\partial F}{\partial \theta}$) and that entrepreneurs are able to grow their size and thus their consumption faster ($\frac{\partial g}{\partial \theta}$). Finally, lower hiring costs mean that newborn entrepreneurs are able to start at a higher initial size as fewer initial resources must be allocated towards hiring the initial workforce, increasing lifetime consumption ($\frac{\partial G}{\partial \theta}$).

The second term corresponds to the same effects that occur due to changes in the capital-labor ratio η arising from the change in θ . In particular, a decline in the capital-labor ratio as a result of search leads to an increase in the profit per unit of capital, and thus per unit of collateral. This higher profit then increases the multiple of collateral consumed, firm growth, and entrepreneurs' initial size, all of which lead to higher consumption. I refer to this as the "Capital Shallowing" externality, and it mirrors the Monopolist externality that due to changes in η impacting households' consumption.

The final step is to add these terms into the first-order condition for θ described

²⁹Although in theory this term can be further simplified by leveraging the fact that CRRA utility allows the various summations to be expressed as geometric series, this obscures rather than illuminates the underlying intuition.

in (39) in order to write the full expression in the case of $\Lambda > 0$.

$$\begin{aligned}
\tau_\Lambda = & \frac{\theta / \int_s^\infty m(a, 0) da}{\frac{d \log v}{d \log \theta} - 1} \left[\underbrace{\left(1 + \frac{d \log p}{d \log \theta} \right) \int_s^\infty \left(\int H(z) \mu(a, z) dz - \mu(a, 0) \right) m(a, 0) p(\theta) da}_{\text{Crowd Out}} \right. \\
& + \underbrace{\theta p(\theta) \int_s^\infty \int \frac{dH(z)}{d\theta} \mu(a, z) dz m(a, 0) da}_{\text{Allocative Efficiency}} \\
& + \underbrace{\frac{\partial \eta}{\partial \theta} \left(\int \int \int \lambda(a, z, y) \frac{dw}{d\eta} j(y) dy dz da \right)}_{\text{Monopolist}} \\
& + \underbrace{\Lambda \sum_{\tau=0}^\infty \int \left(u'(\bar{d}_\tau) \frac{\partial F}{\partial \eta} + \sum_{i=0}^\infty (\beta \bar{g})^i u'(\bar{d}_{\tau+i}) \frac{\partial g}{\partial \eta} \right) \bar{f}_\tau \bar{m}_\tau dz + \beta \left(\sum_{\tau=0}^\infty \int (\beta \bar{g})^\tau u'(\bar{d}_\tau) \bar{m}_\tau \right) \frac{\partial G}{\partial \eta} \underline{f}}_{\text{Capital Shallowing (Entrepreneurs)}} \\
& + \underbrace{\Lambda \sum_{\tau=0}^\infty \int \left(u'(\bar{d}_\tau) \frac{\partial F}{\partial \theta} + \sum_{i=0}^\infty (\beta \bar{g})^i u'(\bar{d}_{\tau+i}) \frac{\partial g}{\partial \theta} \right) \bar{f}_\tau \bar{m}_\tau dz + \beta \left(\sum_{\tau=0}^\infty \int (\beta \bar{g})^\tau u'(\bar{d}_\tau) \bar{m}_\tau \right) \frac{\partial G}{\partial \theta} \underline{f}}_{\text{Market Thickness}} \\
& + \underbrace{\beta \left(\frac{dV}{d\theta_{-1}} + \Lambda \frac{dV_e}{d\theta_{-1}} \right)}_{\text{Anticipation}}
\end{aligned} \tag{56}$$

Plugging this expression in to the first order condition for s yields the an identical planner's optimal search rule but with the additional capital shallowing and market thickness externalities present.

C.3. Relationship to the Hosios (1990) Condition

Given that the main results in this paper have focused on characterizing the efficient level of search, it is natural to wonder if something similar to the famous Hosios (1990) condition holds and if there are (relatively simple) conditions on parameters that lead the competitive allocation to be efficient. This turns out not to be the case in general once all the model features are added; however, building from a simplified version of the model in which the Hosios (1990) condition (almost) holds to the baseline result presented in Proposition 2 is valuable as it provides some intuition for how the main results of this paper fit into the broader search literature.

Some parameters assumptions greatly reduce the model's complexity and elim-

inate some externalities. The first step is to choose $\sigma = 0$ so that workers and entrepreneurs exhibit linear utility and to choose a Pareto weight of 1 so that the planner values all consumption equally (i.e. we are in the case, as in the previous section, where the planner values entrepreneur consumption rather than the case in the main results where the planner values only worker consumption). I then take the capital share parameter α to be 0 (i.e. a linear-in-labor production technology) which eliminates the monopolist externalities related to the capital-labor ratio (refer to 56). Taking the distribution of entrepreneur productivity z to be a point mass eliminates the Allocative Efficiency externality (as entrepreneurs become homogeneous) and, further, letting the collateral constraint parameter $\gamma \rightarrow \infty$ allows entrepreneurs to expand immediately to any size they desire, eliminating the Firm Size externality. Finally, for simplicity I set the cost of search b to 0 and assume that there is no auto-correlation in self-employment earnings.

Because these parameter assumptions leave behind only the Congestion and Market Thickness externalities, it is intuitive that something similar to the Hosios condition may arise. To generate the Hosios condition exactly, we need to make two adjustments to the model.

First, we must adjust workers' outside option in the bargaining protocol. Rather than non-cooperating workers drawing from the distribution of self-employment productivities and engaging in self-employment for a period, we allow them to choose between engaging in self-employment for the period or engaging in job search and "selling" any jobs obtained to other (jobless) workers (with a price equal to the value of the job, something agreed upon by all workers due to linear utility). Although somewhat contrived, this small adjustment is necessary to align the outside option used in wage bargaining with the non-search option available to unemployed workers (which otherwise differs slightly). The second adjustment is to allow the planner to dictate the policy functions of entrepreneurs (which, under these simplifications, boils down to the choice of how many vacancies to post) rather than being constrained to choose values consistent with entrepreneur optimality.

Under these assumptions, the thresholds in income below which individuals opt to search s_c and the income threshold below which the planner would assign

individuals to search s_p are given by

$$\begin{aligned} s_c &= \beta\theta p(\theta) \frac{\chi(z - \tilde{y}_c)}{1 - \beta(1 - \tilde{\lambda})} \\ s_p &= \beta\theta p(\theta) \frac{-\epsilon_{p,\theta}(z - \tilde{y}_p)}{1 - \beta(1 - \tilde{\lambda})} \end{aligned} \quad (57)$$

$$\tilde{y}_x = \int_{y < s_x} y j(y) dy + s_x(1 - J(s_x))$$

where s_c, s_p denote the competitive and planner policies respectively and $\epsilon_{p,\theta}$ is the elasticity of $p(\theta)$. The term \tilde{y}_x , defined for compactness, summarizes the value generated by an unemployed individual — y for those who draw incomes below the threshold and s for those who search.

Here, it is clear that the Hosios condition — equality between the bargaining parameter χ and (the negative of) the elasticity of the matching function $\epsilon_{p,\theta}$ — ensures that the competitive and planner search thresholds align.

With this baseline established, we can undo our two adjustments to the model (i.e. modifying the outside option and giving the planner the ability to dictate the decisions of entrepreneurs) and recover the following thresholds for the unmodified model.

$$\begin{aligned} s_c &= \beta\theta p(\theta) \frac{\chi(z - \tilde{y}_c) - (1 - \chi)(\tilde{y}_c - \bar{y})}{1 - \beta(1 - \tilde{\lambda})} \\ s_p &= \beta\theta p(\theta) \frac{\left(1 + \frac{1 + \epsilon_{p,\theta}}{\epsilon_{v,p}\epsilon_{p,\theta} - 1}\right)(z - \tilde{y}_p) - \left(1 + \frac{1}{\epsilon_{v,p}\epsilon_{p,\theta} - 1}\right)\left(\lambda + \frac{1 - \beta}{\beta}\right)\frac{c}{p(\theta)}}{1 - \beta(1 - \tilde{\lambda})} \end{aligned} \quad (58)$$

Relative to (57), two adjustments appear, one in the competitive cutoff (blue) and one in the planner's cutoff (red). These make clear why the previous model modifications were necessary to generate the Hosios condition exactly. The blue term appearing in the equation for s_c arises as a result of the bargaining protocol, which imposes outside options for workers that are different than the options available to the unemployed. This term adjusts for this fact, leading to a slightly lower cutoff (i.e. $\tilde{y}_c - \bar{y}$ is positive).³⁰

The second modification, appearing in red in the equation for s_p , arise from

³⁰As we will see shortly, this term “disappears” once the cutoffs are written in wage terms but, for now, thinking in terms of productivity behooves comparison between (57) and (58).

the fact that the planner is now only able to dictate the decisions of households and, consequently, is constrained by the fact that the number of vacancies posted responds to changes in the vacancy filling probability $p(\theta)$. As a result, the planner cares about the “net” elasticity of θ with respect to the number of searchers, given by $\frac{1}{\epsilon_{v,p}\epsilon_{p,\theta}-1}$, which when multiplied by the elasticity of the job finding probability with respect to θ , $1 + \epsilon_{p,\theta}$, yields the net change in the job finding probability due to a change in search. For the planner, the surplus generated by the marginal searcher is equal to the surplus generated by the average searcher ($z - \tilde{y}_p$) adjusted by this net congestion effect.

The remaining red terms involving $\frac{c}{p(\theta)}$ also arise as a direct result of the removal of the planner’s ability to dictate vacancy postings. In the modified model of (57), the impact of vacancies on entrepreneur consumption was accounted for in the first-order condition for vacancies. Now that planner can only control θ through search decisions, this impact is incorporated into the planner’s optimal decision rule for search (and arises via the same net elasticity $\frac{1}{\epsilon_{v,p}\epsilon_{p,\theta}-1}$). This is the Market Thickness externality of search.

The final step in bridging the gap between the Hosios condition in (57) and the decision rule in the full model (i.e. 56) is to write (58) in wage terms using both the wage bargaining equation ($w = \chi z + (1 - \chi)\tilde{y}$) and the optimal vacancy posting condition ($z - w - (\lambda + \frac{1-\beta}{\beta})\frac{c}{p(\theta)} = 0$) and do some simple rearranging.

$$\begin{aligned} s_c &= \beta\theta p(\theta) \frac{w - \tilde{y}_c}{1 - \beta(1 - \tilde{\lambda})} \\ s_p &= \beta\theta p(\theta) \frac{w - \tilde{y}_p}{1 - \beta(1 - \tilde{\lambda})} + \tau \end{aligned} \tag{59}$$

$$\tau = \frac{1}{\epsilon_{v,p}\epsilon_{p,\theta} - 1} \left(\underbrace{\frac{(1 + \epsilon_{p,\theta})(z - \tilde{y}_p)}{1 - \beta(1 - \tilde{\lambda})}}_{\text{Congestion}} - \underbrace{\frac{(\lambda + \frac{1-\beta}{\beta})\frac{c}{p(\theta)}}{1 - \beta(1 - \tilde{\lambda})}}_{\text{Market Thickness}} \right)$$

This expression for the cutoffs is, finally, the simplified model’s equivalent of the search decision rule in Proposition 2 or (more completely) in equation (56). The expressions for the Congestion and Market Thickness externalities are simpler and the Firm Size, Capital Shallowing, and Efficiency externalities are zero as a result of the simplifying parameter choices. We can then relax these choices one-by-one

to add these externalities back to τ and eventually end up at the expression in (56) and, from there, set the Pareto weight on entrepreneurs' utility to 0 and apply linear utility ($\sigma = 0$) to end up with the expressions in Proposition 2.

D. Details on Model Estimation and Quantitative Exercises

Many model parameters are chosen to match values typical in the macroeconomics, are taken from external sources, or are estimated directly. These are displayed in Table D.1, along with their values and sources. The discount rate β is chosen to match an annual discount rate of 0.95. Because a model period corresponds to two weeks, this corresponds to a value of $0.95^{\frac{1}{26}}$. The rate of return on worker's savings R is taken to be exogenously equal to $0.9^{\frac{1}{26}}$. The assumption that the return to savings is less than one is typical models of developing countries (see e.g. [Donovan 2021](#), [Fujimoto](#), [Lagakos & VanVuren 2023](#)) and representative of the fact that households in these countries lack access to formal investment with positive returns. The value of 0.9 matches an annual inflation rate of roughly 10 percent, roughly consistent with World Bank estimates of inflation in Ethiopia over the last few years; thus the model asset a most closely reflects cash holdings. The capital share of income is set at 0.33 as is standard.

For the matching function, I use a simple generalized urn-ball matching function so that $p(\theta) = \frac{1-e^{-\zeta\theta}}{\theta}$. This particular choice of functional form is unimportant beyond the fact that it introduces a free parameter that can be used to target any desired elasticity for p in the model steady-state.³¹ Absent detailed estimates of this elasticity in the context of Addis Ababa and lacking the necessary data to estimate it, I choose ζ to generate an elasticity of -0.3. This is a fairly typical value and roughly in line with the estimates of [Hall & Schulhofer-Wohl \(2018\)](#) for the United States.

The interest rate faced by entrepreneurs is disciplined using World Bank MIX Market data containing financial information on microcredit providers in Ethiopia. Yields on loans from microfinance institutions range from 20 percent to 30 percent with negligible loan loss rates (typically less than one percent). Combining this rough average of a 25 percent annual return with 8 percent depreciation yields a depreciation-inclusive user cost of capital of 33 percent annually. This value is high relative to developed countries but is fairly typical for developing countries

³¹A functional form exhibiting a constant elasticity, such as Cobb-Douglas, would be ideal, but the use of discrete time limits sensible choices for p to those that lead both $p(\theta)$ and $\theta p(\theta)$ to be bounded between zero and one.

(see e.g. [Banerjee et al. 2015](#), who document similar values in multiple countries including Ethiopia).

Collateral constraints are measured directly using data from the Ethiopian portion of the World Bank Enterprise Survey for the year 2015. The average collateral requirement reported by firms is slightly larger than 350 percent of loan value, meaning that a firm that owned 350,000 Birr worth of capital could pledge this as collateral and finance a loan for an additional 100,000 Birr of capital. Thus the implied value for γ is $1 + \frac{1}{3.5} = 1.29$. The Enterprise Survey is also used to estimate the entrepreneur survival probability Δ . Because productivity is constant for the life of an entrepreneur, entrepreneur death is the only reason that firms will shutdown in steady state. Consequently, the steady-state distribution of firm ages is geometric with decay parameter Δ whose value can be recovered through the simple maximum likelihood estimation. In this case, the estimate for Δ is given by $1 - \frac{1}{\hat{\mu}}$ where $\hat{\mu}$ is the sample average firm age, yielding an annual value for Δ of 0.92.

The self employment productivity process also comes directly from data. This productivity is modeled as a simple binary Markov process, drawing on the fact that earnings for those without permanent wage jobs are highly bimodal at a fortnightly frequency (seen in the high-frequency data of [Abebe et al. 2021a](#), described below). Such bimodality seems to stem from the fact that opportunities for self employment (or, often in the case of Addis Ababa, temporary "gig-style" labor that functions similarly to self employment), and many individuals report neither working nor searching in a given period, presumably earning very little.

One advantage on using a binary income process instead of a more typical AR(1) is that transitions in and out of this idle state can be observed and measured directly. Using fortnightly data on work and searcher activities (described in the next section), I estimate the transition probabilities from engaged in self employment or temporary work to idleness and back. Although there is no reason for these transitions probabilities to be identical, the estimated value for both is approximately 11 percent. While average self employment earnings (i.e. the productivity parameter A_s) are estimated using SMM, the ratio of earnings in the low productivity state to the high productivity state is chosen to match the standard deviation of self employment earnings observed in the data. In particular, I isolate the transitory, idiosyncratic variance of earnings by regressing (log) earnings on individual and week fixed effects and calculating the standard deviation of the

residuals (similar to the process employed in [Lagakos & Waugh 2013](#)). Conditional on the transition probabilities, there is a one to one correspondence between the standard deviation of income and the ratio of interest.³² The estimated ratio is 0.38 corresponding to an estimated standard deviation of .48.

Finally, the distribution from which newborn entrepreneurs draw their productivity is chosen to be an upper-truncated Pareto distribution (truncated as a bounded support for productivity is required for steady-state equilibrium to exist in the model). I set the lower bound of the distribution to a small but arbitrary number; because entrepreneurs endogenous shut down below a threshold productivity level and the truncated Pareto distribution is scale-invariant, the lower threshold has no impact on model outcomes as long as it is below the shutdown threshold. The tail parameter is set to unity. It is worth noting that because of upper truncation, the mean and variance of productivity remain finite. The upper bound \bar{z} is included in the SMM estimation, described in the main text.

Table D.1: Directly Estimated Parameters

Parameter	Value	Description	Source
β	$.95^{\frac{1}{26}}$	Discount rate	Standard value
R	$.9^{\frac{1}{26}}$	Return to savings	10% annual inflation
α	.33	Capital share	Standard value
r	$1.33^{\frac{1}{26}} - 1$	Capital cost for entrepreneurs	MIX Market
γ	1.29	Collateral constraint	World Bank ES
Δ	$.92^{\frac{1}{26}}$	Entrepreneur death prob.	World Bank ES
$M(y)$	$\begin{bmatrix} .89 & .11 \\ .11 & .89 \end{bmatrix}$	High and low y trans.	Abebe et al. (2021a)
$\frac{y_l}{y_h}$.38	Ratio low to high productivity	

This table displays the model parameters that are estimated directly as well as their values and sources. To help comparisons to typical values, parameters are displayed in annual terms. See the discussion for details on each parameter.

³²For a symmetric transition matrix, as is the case here, this correspondence is given simply by $\frac{y_l}{y_h} = e^{-2\sigma}$
